In the process cycle valves B, C, and D are closed, isolating all the sections.

The duration of the process cycle is 4–10 min, depending on the contaminants to be removed, and is controlled either by a timer if the contaminants are fixed or a controller in the effluent stream, if the contaminants vary considerably over short intervals.

Valve A opens and resin drops in the pulse section simultaneously with the removal of contaminants in the loading section, regeneration of loaded resin in the strip

Fig. 1. *Schematic diagram of Chem-Seps continuous counter-current ion exchange contactor*

Valve positions during cycles:
(a) Run cycle. Valves A, E, F, G, I, K open; valves B, C, D, H closed
(b) Pulse cycle. Valves B, C, D, H open; valves A, E, F, G, I, K closed

section, and rinsing of regenerated resin in the rinse section. As the resin drops through the valve A, it is backwashed to remove the suspended solids or resin fines. Removal of these fine particles is important to avoid the unnecessary pressure drop in the bed and plugging of the distributors.

At the end of process cycle, all flows going into and out of the unit are automatically shut off. The valve A closes and valves B, C, and D open in proper sequence. A slug of water enters through valve H, a predetermined incremental volume of resin moves into the regeneration section, an equal volume of regenerated and rinsed resin enters the bottom of the loading section, and an equal volume of the loaded resin leaves the top of the loading section and goes into the overflow section. (The resin movement is plug flow with the Reynold's number being in the laminar region of the curve, and no fluidisation occurs during the pulse cycle.) The total time required for proper sequencing of valves and the movement of resin is 20–30 sec. At the end of this period, the valves B, C, and D close and valve A opens. The solution valves open and normal steady state operation begins. All valves are interlocked and properly sequenced.

Special features

Down flow

The feed moves downward and the resin moves upward in the loading section. The down flow of feed overcomes the handicap encountered in up flow systems. The up flow of feed requires a certain minimum flux during the process cycle to lift the bed and keep it in suspension. If a certain flux is not maintained, resin begins to 'churn' in the loading section. In the down flow system, resin drops in the loading section by gravity, and flow of feed in the downward direction further keeps the resin settled. The maximum flux in down flow is 60 gal/min/ft^2 and there are no limitations on the minimum flux, compared with a minimum flux of 20–30 gal/min/ft^2 in up flow systems.

Another advantage of down flow is the use of untreated water during pulse and backwash. The water which is used for pulse goes out in the waste. The resin in the pulse section is fully loaded, whereas in an up flow system the resin in the pulse section is fully regenerated and rinsed, thus use of treated water is mandatory.

The only treated water requirement is the rinse water which equals the volume of resin moved.

One other advantage of down flow is that the liquids with higher specific gravity are always at the bottom part of the loop; thus it is easy to control the interfaces and obtain concentrated wastes.

The performance of a down flow system using low-density resins is superior to up flow performance with similar resins. A weakly basic resin such as Amberlite IRA-93 in hydroxide form when transferred after regeneration and rinsing in an up flow system is an example of such a situation. The settling of the resin in the pulse section requires a considerable time, and slows down the production rate in an up flow system. However, in a down flow system the resin when transferred to the pulse section is in sulphate or chloride form, which is of greater density, and settling presents no problems.

Use of slurries

Slurries can be used for regeneration in Chem-Seps continuous counter-current ion exchange because of the inherent advantages of the moving-bed and counter-current flows. Suspended solids will plug up the conventional ion-exchange system and it is impossible to use lime as regenerant for weakly basic resins, whereas slurries do not present any particular problems in the Chem-Seps single-loop system and are easily handled by using special distributors.

Reduction of waste volume

The resin is thoroughly rinsed in a Chem-Seps single loop system with an equal volume of water owing to the inherent efficiencies gained by counter-current flows in a single loop. The liquid interfaces are precisely controlled by using various interface controllers and excess water is eliminated from the waste. The volume of waste in a standard de-mineralisation process is reduced to one-tenth of the volume by using Chem-Seps CCIX instead of a conventional de-mineraliser.

Reduction of operating costs

The regenerant chemicals required in Chem-Seps CCIX are 20–100% over stoichiometric amounts; compared with 2- to 10-fold excess over stoichiometric amounts required in conventional systems.

Applications

De-mineralisation of boiler feed and process water

Usually the largest single cost in operating an ion-exchange de-mineraliser is the cost of chemicals used for

regeneration. A conventional fixed-bed ion-exchange de-mineraliser will be found to use a 100% or more excess of regenerant chemicals over the stoicheiometric amounts. The counter-current flow efficiency of continuous ion exchange has given a reduction of regenerant consumption to within 10–25% excess over stoicheiometric amounts. An example of a continuous de-mineralisation plant installed in a fertiliser complex in Canada includes a strongly acidic cation unit followed by an atmospheric decarbonator with a weakly basic anion unit and a strongly basic silica polisher (see Fig. 2). The untreated feed water to this system contains from 1200 ppm total dissolved solids (*TDS*) to as high as 1800 ppm *TDS*, depending on the season. Approximately 65% of the *TDS* is sodium. The effluent requirement is 5 ppm *TDS*. The real aim for the system is to maintain the chloride content in the effluent to ~3 ppm. Sodium tailings in this system are critical. The cation unit is regenerated with 10–12% nitric acid. This acid was selected because it is an 'in-plant' product with a relatively low cost. It is of interest that the excess nitric acid may be piped to the blending plant so that the nitrate values are actually calculated as part of the product of this fertiliser complex. The regenerant for the weakly basic anion unit is 3–5% NH_3 as ammonium hydroxide solution. Ammonia is a product of this plant, and thus available at low cost. This unit (see Fig. 3) serves as an example of water treatment that was considered to be impractical by conventional fixed beds. Sodium tailing is a common problem in de-mineralisation and is the key factor in control of conductivity and pH of water in the cation unit and the final water. The equipment for continuous detection of sodium is sensitive to very low levels. Sodium removal is over 99·4% and is reduced from 500 ppm to less than 3 ppm.

Since a weakly basic resin is used in this installation the down flow system is the 'key' to the production rate. As already mentioned, the resin transferred to the pulse section is in sulphate and chloride form, and settling of the good resin is achieved in 2–3 min which helps maintain the fast production rate.

The operating and capital cost comparisons between a conventional and Chem-Seps continuous counter-current ion exchanger are given in Table I.

Fig. 2. *Typical layout for de-mineralisation*

The savings in chemical cost alone amount to $48,500 per year.

The resin inventory in continuous counter-current ion exchange is 20% of conventional fixed-bed systems.

Conventional fixed-bed equipment designed for regeneration every 8 h will require 'on stream' two cation units of 9 ft dia. × 4 ft bed depth, and two 'off stream' on regeneration and the same number of anion units with 8 ft dia. × 3 ft bed depth.

The Chem-Seps continuous counter-current ion-exchange units are 10 ft × 10 ft base and 27 ft high, one train occupying 200 ft^2 or 5400 ft^3. The fixed beds will require 550 ft^2 and 8000 ft^3. The piping of so many fixed-bed units is an extensive operation.

For a high degree of removal of sodium (to less than 3 ppm) 100% excess over stoicheiometric amounts of nitric acid is used. A conventional system would use 350% excess over stoicheiometric amounts at 10 lb/ft^3 of H_2SO_4 or 38·6 lb HNO_3/1000 gal using 6 lb/ft^3 at 250% excess over stoicheiometric amounts. Recently, at this particular installation, the cation resin has been mixed with a weakly acidic resin Amberlite IRC-84. The percentage of weakly acidic resin is being gradually increased to 30%. In the next few months the weakly acidic percentage will be increased, and it is hoped that nitric acid consumption can be reduced to less than 50% when the optimum ratio of the two resins has been reached in the operation. This will result in savings worth $10,000 per year using the normal 'in-plant' cost of nitric acid.

Fig. 3. *Continuous de-mineralisation plant of fertiliser complex in Canada*

TABLE 1

Capital and operating costs comparisons of a conventional and a Chem-Seps continuous counter-current ion exchanger

Basis *TDS* 1500 ppm
Flow 880,000 U.S. gal/day

	Conventional fixed beds	Chem-Seps CCIX
Capital cost:		
Equipment cost (actual bid) delivered uninstalled	$130,000	$120,000
Installation and start-up	$ 26,000	$ 12,000
Total investment	$156,000	$132,000
Major equipment:		
Total resin inventory		
Strong acid cation		
Weak base anion	950 ft³ 550 ft³	190 ft³ 190 ft³
Operating cost		
Chemical:		
NH_3		
HNO_3	2·92 lb/1000 gal	0·575 lb/1000 gal
NH_3 at 3c/lb	38·2 lb/1000 gal	22·1 lb/1000 gal
HNO_3 at 1·75c/lb	50·07	50·02
Cost of chemicals/1000 gal	50·67 50·76	50·59 50·41
Resin attrition:	Assume equal for both case	
Savings/day		$11·13/day
Savings/year at 365 days/year operation		$48,500/year

Weak resins and mixed beds

The use of mixed resin beds or weak- and strong-type cation resins in order to lower acid regenerant costs is becoming a widely used practice. This practice already used in fixed-bed design also fits well with continuous counter-current cation design. The mixture usually contains a higher fraction of the weak-type resin. This fraction is greater than the fractional amount of bicarbonate in the water to be treated. The additional amount of weak-type resin provides for the migration of alkaline earth elements from the strongly acidic resin that use some of the exchange capacity of the weak-type resin. A treatment of waters containing high quantities of bicarbonates, in the region of two-thirds of the total anion content, allows use of stoicheiometric amounts of sulphuric acid regenerant. The second hydrogen atom on the sulphuric acid molecule is poorly ionised and is lost in regenerating strongly acidic resins but is effective in regenerating the weak-type resin. An example of an installation of weak- and strong-acid types of resin is indicated in Fig. 4. This water is about 80% bicarbonate and most of the cation is sodium. The resin mixture is 75% Amberlite IRC-84 and 25% Dowex 50W-X8. Stoicheiometric use of sulphuric acid was demonstrated in pilot tests and 25% excess was guaranteed for this installation. Samples taken within the strip section show complete utilisation of free acid.

Pilot tests were also run for a water that contained anions made up of 85% SO_4^{2-} and Cl^- and 15% bicarbonate. Sulphuric acid consumption was between 25 and 50% over the stoicheiometric amount. It was noted that a disproportionate amount of hardness ions

Fig. 4. *Typical installation of weak- and strong-type resin plants*

were associated with the weakly acidic resin relative to the amount of bicarbonate present. This is one reason for using a preponderant amount of the weakly acidic resin. It is an effect not realised in a 'layered' fixed bed.

Another reason for using a bulk amount of weakly acidic resin is the lower utilisation capacity at high production rates, since the exchange rate is lower if the utilisation capacity is increased. The typical span of capacity loading planned is 0·0–0·5 equiv/l., whereas the strong-type resin might be loaded to 80–90% of its total capacity.

The typical high degree of expansion and contraction of this resin is of no concern in a Chem-Seps single loop continuous counter-current contactor.

Another factor in favour of Chem-Seps continuous counter-current ion exchange was low resin capacity utilisation, since there is over 95% sodium in the cations. The theoretical capacity for Amberlite IRC-84 for this application using conventional system and manufacturers data is 7·5 kg/ft³. If the units are designed to normal requirements of regeneration once every 8 h, it would require a total resin inventory of 1100 ft³ to treat 750 gal/min. The total resin inventory in two Chem-Seps continuous counter-current ion-exchange units to treat 375 gal/min each is 150 ft³.

The cost of resin alone, if fixed bed units were used was $55,000.

In this application the system provided by Chem-Seps has more reliability than the conventional fixed-bed system, since there are two continuous units each performing the full task, compared with only one fixed-bed unit in operation with one constantly in regeneration.

Slurry regenerant

Lime slurry is a low-cost regenerant. If lime slurry could be used effectively without causing plugging of the equipment by the very high content of solids in the regenerant feed stream, it was reasoned that this would reduce the cost of anion regenerant. In earlier work on the extraction of uranium, a slurry of about the same solids content as would be found in a lime slurry regenerant feed stream was used. Some work was done in the past with lime slurry in the exploration of a flowsheet to produce caustic soda by ion exchange. The use of lime slurry as an anion regenerant is hazardous since precipitation of calcium carbonate and calcium sulphate within the resin bed would mean a prolonged shutdown. In the treatment of water with a high bicarbonate content, the hazard of calcium carbonate is eliminated by the use of an effective decarbonator in front of the anion unit. The fear of precipitation of calcium sulphate has been groundless in the Chem-Seps single loop design. It has been demonstrated that anion resin in the sulphate form may be effectively regenerated with lime slurry without precipitation of calcium sulphate within the moving bed.

Regeneration of weakly basic anion resins with lime slurry is effective. An excess of 10% over the stoicheiometric amount is standard practice.

The Sul-biSul process is an example of an effective demineralisation system with low operating cost; in it, lime slurry is used for neutralisation of free acid formed in the regeneration step. The introduction of lime slurry keeps the volume of waste down. Chem-Seps is one of the licensees of the process.

The maximum capacity is only half the theoretical capacity of anion resin. The anion resin inventory for a half million gallon per day plant, by Chem-Seps continuous counter-current ion exchange, would be 250 ft³ for a water containing 1500 ppm of sulphates, but for conventional system, the resin inventory would be 1200 ft³ if the units are regenerated every 8 h.

For an application using Sul-biSul, the Chem-Seps continuous system is highly efficient and reduces the capital cost.

DISCUSSION

Resin attrition

In a system where valves are closed on pipelines full with resins, is not resin attrition a considerable problem?

It is 'assumed' that valves closing in a bed of packed resin will cause considerable attrition. Resin life up to ten years has been measured in a unit with four valves opening and closing every five minutes.

Uranium Plant

As Mr. Chopra mentioned, my company has been carrying out experiments in the Western Uranium Fields of the U.S.A. with a Higgins Ion Exchange Contactor. Uranium is extracted from a sulphuric acid-process leach pulp containing 7–8% suspended solids. The pulp is desanded and contains a considerable amount of wood pulp in addition to the clay fraction of the uranium ore. The wood pulp is a common problem associated with underground mining of the ore as anyone in the uranium mining can testify. More problems may be expected from the wood fibres which do not separate too well in either hydrocyclones or screens. The contactor was operating successfully for up to 98 hours, tests being terminated by reasons not connected with the contactor.

Author's reply. This is not the first time slurries have been handled in Chem-Seps equipment. See AEC Report, ORNL-2308.

Uranium (William Ruby & Co.)—Of the speakers this morning only M. Bouchard's paper mentioned the use of continuous ion-exchange plants for mixed bed applications. In view of the extremely low leakage possible from mixed bed plants at very high regenerant efficiencies could the three authors mentioned above,

explain whether their processes are applicable to mixed bed operation and if so, in what way their basic process would be changed?

Author's reply. We have done a considerable amount of test work related to mixed bed continuous ion exchange. We very definitely are expecting to offer a system after we finish pilot plant testing. Our main goal has not been to make a high degree polisher, but a bulk demineraliser using weak type resins and stoicheiometric regeneration.

Mr. R. C. Clayton. There is no reason why the system described in my paper cannot be adapted for mixed bed applications provided a satisfactory resin separation stage is introduced.

Dr. D. G. Stevenson. Fluidised bed systems cannot of course be used for mixed bed operation in the normally accepted sense. Normal grades of anion and cation resin will segregate in the bed. Alternatively, if the size ranges are chosen so that a true mixture of the resins is obtained, it will not be possible to segregate them for regeneration. However, it is expected that a useful system will prove possible whereby a layer of cation/anion resin is present above each distributor plate. It would not be difficult to have for example four double beds in this manner. Performance should be very much better than that of a single cation/anion combination. The particular resin transfer system developed for this work is capable of transferring both components in any such dual bed.

Dr. R. Hönigschmid-Grossich (c/o Dynamit Metal A.G.).—Question to all who presented papers on countercurrent systems: what happens when valves, pumps etc. break down; can this fact not minimise the advantage of this system in relation to normal 'old-fashioned' ion exchange equipment?

Author's reply.—In this day and age, what is the problem in choosing reliable pumps, valves, and other component parts? I have 172,000 miles on my automobile. Any well built and well cared for piece of machinery can do as well.

Mr. R. C. Clayton.—It is cheaper to produce plant in a series of standard sizes or modules, and any water requirement will frequently be supplied by two or more continuous plants. Any outage time can thus be catered for by temporarily increasing the flow through the other modules. In fact, valve failure in ion-exchange plant is a rarity, and there is no reason why it should be more common on C.I. plant provided correct maintenance procedures are followed.

INTRODUCTION

Evaporation as a desalination tool is applicable for feed solutions with higher concentrations of dissolved solids. The concentration of dissolved solids at which evaporation becomes competitive with reverse osmosis or EDR will vary from case to case depending on:

- Size of Installation
- Cost of Electricity
- Salt Composition in Solution
- Recovery of Water Required
- Cost of Disposing of Brine Concentrate
- Credits for Useable By-Products

According to a LURGI brochure inserted below, the crossover between economics favoring R.O. and evaporation occurs at around 10,000 mg/l TDS. There are, however, several R.O. plants that were selected for seawater (35,000 mg/l TDS) desalination at much higher TDS levels than this, so clearly other factors play a role.

One way to get the "best of both worlds" is to use R.O. for primary concentration and evaporation for final water recovery from the R.O. brine and for final volume reduction of the concentrate for less expensive or more convenient disposal. At a metallurgical plant (platinum and base metal refinery) at Rustenburg, an acid metallurgical solution is neutralized and evaporated to yield a salable Na_2SO_4 product avoiding the need for any brine disposal method.

The problem with installing two processes in tandem for water recovery is that then there are two plants with two types of technology to maintain and operate instead of one which adds complications, but in some circumstances, it has proven to be the most economical way to achieve zero discharge. Where tandem systems using R.O. for primary concentration followed by a smaller capacity evaporator system are to be installed, it would also be attractive to have the option of using one contractor/engineering company to be responsible for the total water recovery and salt disposal package. There are not many companies that have experience in more than one type of desalination technology, particularly not in a mineral processing environment. The following companies are known to have that experience, however:

The basic principles of evaporative desalination are outlined below in an excerpt from SCHUTTE (1983). There are several innovative approaches to evaporation and condensing as illustrated in excerpts from various company brochures that follow. For each case, a potential user is well advised to "shop around" to obtain several quotes, bearing in mind too that he may also be comparing "Mercedes Benzes with Fords" and that, in some cases, a price differential may be justified.

Because desalination is a specialized field, it would always pay to retain a consultant to review the quotations tendered for a given job, particularly a consulting firm with a wide breadth of experience. One such consulting firm is the Resources Conservation Company listed above who has installed a wide variety of desalination plants around the world for several different industries, and who has developed several highly innovative technologies such as, for example, slurry seeded evaporation. This company is also an experienced water resource management firm who may be able to devise a water management plan to minimize or avoid the need for desalination altogether. The following excerpt from their brochure shows one example where improved water management and a three-step desalination processing train (R.O. and evaporation) achieved zero discharge for a client.

Wastewater inventory reduced by 50%

A significant and unexpected growth of wastewater was about to cause major problems at a southeastern utility's 1,900-MW coal-fired station. RCC moved onsite, analyzed all major streams, and produced a near-term solution to intercept and divert rainwater and reroute some existing wastewater. Simultaneously, we developed long-term alternatives to better manage the internal streams. Now operating, our water management system has not only reduced accumulated wastewater but has also allowed zero liquid discharge.

Finally, at the end of this chapter, inserted is a pamphlet and a publication by GORE (?) describing a highly innovative new approach to evaporative desalination processes that employ a membrane. The Gore-Tex membrane disttillation is not yet working commercially but offers exciting potential in the future of desalination technology.

CHAPTER 5

DISTILLATION

5.1 Introduction

Desalination can be effected by different processes including distillation, reverse osmosis, electrodialysis, ion exchange and freezing. Although the large scale application of these processes for water production is relatively new, distillation was employed more than a hundred years ago on board ship for the production of potable water from sea water. However, distillation only became commercially viable on large scale with the introduction of the multi stage flash process in 1958.

In this chapter a brief description is given of the different distillation processes, advantages and disadvantages are given together with process requirements, practical experience and economic considerations. In the following chapters the other desalination processes are discussed.

5.2 Process description

There are three essential steps involved in desalination by distillation, i.e. production of vapour from the feedwater, removal and transportation of the vapour to the condensor and condensation of the vapour. These processes are incorporated in a number of different distillation processes configurations i.e. multistage flash, multiple effect and vapour compression.

5.2.1 Multistage flash (MSF)

A conceptual design for a MSF distillation plant is shown in figure 5.1 (USAID 1980). The basic principle is that pre-heated seawater enters the evaporation chamber under reduced pressure, resulting in flash boiling of part of the seawater. The vapour produced by flashing is then condensed on the outside of tubes conveying cooler seawater to the hot end of the plant.

The incoming seawater passes first through a heat rejection stage and is then heated in the heat recovery sections of each subsequent stage. Before entering the first stage the seawater is heated to its maximum temperature by external steam. The feedwater then passes through the various stages where flashing takes place. The vapour passes through demisters and is condensed on the outside of tubes conveying seawater to the hot end of the plant. The fresh water formed by condensation is collected in each stage and is passed to subsequent stages where it is also flashed to recover heat for preheating of the feed.

The number of stages employed in a MSF plant largely determines its efficiency. The normal range is from 20 to 50 for commercial plants. The more stages the higher the fuel efficiency but the higher the capital costs also.

MSF plants are used exclusively for seawater desalination and have captured by far the largest part of this market. The installed capacity of MSF plants in 1980 was $4,8 \times 10^6 m^3/d$ which accounted for 67% of the world's total installed desalination capacity (Techno-Economic Services 1981). The main reason why MSF has done so well is that these plants can be constructed with large capacities - 25 000 m^3/d not being uncommon and the technology and expertise is available to construct much larger size plants. Another main advantage is that boiling does not take place on the heating surface but the seawater flash boils instead. These plants require well skilled operators and great care during start up.

FIGURE 5.1 Conceptual diagram of the multistage flash (MSF) process. (USAID 1980)

5.2.2 Multiple-effect evaporators

A conceptual design for a multiple-effect vertical tube evaporator (VTE) is shown in figure 5.2 (USAID 1980). In each effect steam is condensed on one side of a tube and the heat of condensation is utilized to evaporate water on the other side of the tube wall. The cascading use and reuse of the heats of vapourization and condensation is made possible by progressively reducing the pressure in each subsequent effect. This allows the brine to boil at progressively lower temperatures as it flows through the plant.

The same principle is also used in horizontal tube multiple effect configurations. Only limited experience with horizontal tube units is available compared to the vertical tube configuration.

The first multiple effect units utilized submerged tube heaters but due to problems with scaling on the submerged tube surfaces and the lower evaporation efficiencies this configuration is not used any more for large scale applications.

Low temperature multiple-effect distillation offers a number of advantages such as reduced scale forming and corrosion but in spite of all these potential advantages it has not found large scale application.

5.2.3 Vapour compression

Figure 5.3 (USAID 1980) shows a conceptual design for a vertical tube vapour-compression process. This process differs from other distillation processes in that it does not use an external heat source as primary energy source, but utilizes instead mechanical energy to drive a compressor to increase the vapour pressure of the water and thus its condensing temperature (a steam ejector may also be used). Condensation takes place on one side of a tube which acts as heat transfer surface while feed is evaporated by the heat of condensation on the other side of the tube.

Notes: 1. This drawing is greatly simplified.
2. A final condenser such as shown on Figure 3-10 is necessary for operation.

FIGURE 5.2 Conceptual diagram of a vertical-tube evaporator (VTE). (USAID 1980)

A vertical-tube vapor compression unit to concentrate brine from a coal-fired generating station in southwestern USA. This unit processes about 0.225 mgd [852 m^3/d] of brine with a freshwater recovery of up to 98%.

FIGURE 5.3 Simplified flow diagram for a vertical-tube vapor-compression process. (USAID 1980)

The compressor compresses the vapour, raising its condensation temperature and at the same time lowers the pressure on the feedwater thus reducing its boiling temperature. The only major energy input during operation is that required to drive the compressor, since the heats of condensation and vapourization are being recycled across the heat transfer surface. Feed heaters are normally only required during start-up and once the unit is running only mechanical energy is required.

The two configurations used in vapour compression units are vertical tube falling film and horizontal tube spray film types.

A specialized type of vertical tube vapour compression plant is the brine concentrator. It employs vertical titanium tubes through which the brine or wastewater is recirculated in a slurry containing calcium sulphate or other crystals. In this way scale formation on the heat transfer surfaces is minimied since precipitation preferentially takes place on the crystal surfaces. Very high concentrations of dissolved solids can be handled in this way and water recoveries of up to 98% can be achieved. A similar process but using horizontal tubes is also available.

Low temperature vapour compression distillation for the desalination of seawater is highly energy efficient. It has a specific energy consumption of about 10 kWh/m^3 which is of the same order as for reverse osmosis without energy recovery (Hoffman and Ophir 1982). These plants operate within the temperature range of 30-70°C which results in low scaling and low corrosion rates and therefore require only fairly simple feed pretreatment.

These units utilize a special aluminium alloy suited for seawater use. They have been operating successfully as low temperature multi effect vapour compression plants.

The performance factor (kg product/M J energy input) of vapour compression plants is high (8,5) compared to multiple-effects (7) or multi-stage flash (5). However, they are limited in size to about 1000 m^3/d per unit by the size of commercially available compressors and therefore they do not have the economy of scale with respect to capital cost for large size plants.

Vapour compression units are available as skidmounted packaged units with capacities ranging from small to about 1000 m^3/d. For larger capacities a number of units have to be used.

5.3 Distillation process characteristics

5.3.1 Efficiency

The efficiency of a distillation plant is measured by the mass of water produced per unit of heat energy and can be expressed in terms of performance factor or economy ratio.

(i) Performance factor is expressed as kg water per MJ energy input.

(ii) Economy ratio (or gained output ratio GOR) is the ratio of kg water produced to kg of heating steam supplied. For vapour compression units using mechanical power a steam equivalent based on the energy input per kilowatt hour is used to calculate the performance factor.

The performance factor of multi-stage flash plants is restricted to about 5kg/MJ due to the limited number of stages that can be installed between the hot and cold ends of the plant. Calcium sulphate scale formation restricts the upper temperature to about 121°C.

Multiple effect plants may be built with performance factors as high as 8 kg/MJ but construction of large MED plants is impeded by a lack of prototype units.

The efficiency of vapour compression units vary from 25-50 kWh/m^3 product but recent developments in low temperature vapour compression could bring this figure down to 10 kWh/m^3 (Hoffman and Ophir 1982).

5.3.2 Scaling in distillation plants

One of the most serious problems limiting the efficiency of distillation plant is scale formation due to precipitation of calcium carbonate, magnesium hydroxide and calcium sulphate. All of these have inverted solubility characteristics and become less soluble as the temperature is raised.

The control of scale formation is essential in any desalination unit if it is to be operated for long periods at or near optimum efficiency. Two methods are being used for scale control i.e. acid treatment and chemical addition to prevent formation of hard scale. Acid addition is used to remove the alkaline scale forming potential by removing bicarbonate ions.

$$HCO_3^- + H^+ \longrightarrow CO_2 + H_2O$$

Although effective in preventing alkaline scale formation, acid addition results in increase corrosion rates. Corrosion can be reduced by removing dissolved oxygen in the feedwater to the plant to very low levels (0,05 mg/l) by vacuum deaeration and/or the addition of reducing agents such as sodium sulphite.

The addition of chemicals such as polyphosphate based products and more recently certain polymers retards the formation of alkaline scale and is used extensively in distillation plants. These "threshold" additives distort the crystal structure and prevent the formation of hard scales. The advantage of using inhibitors rather than acid treatment in distillation plants is that the rate of corrosion is reduced markedly.

None of these methods is effetive in the control of calcium sulphate scale formation in distillation plants. These plants are therefore operated within the calcium sulphate solubility limits although higher efficiencies may be obtained at higher temperatures.

Materials of construction is the one item which most significantly influences the capital cost and life of distillation plants. Distillation plants are exposed to high temperatures, concentrated brine solutions and often corrosive chemicals and great care must therefore be taken in selecting materials of construction.

5.3.4 Reliability

Distillation plants can be built to be extremely reliable in operation. However, reliability can also be poor as a result of poor design, selection of construction materials or poor operation.

5.3.5 Product water quality

Product water from a distillation plant is extremeley high, usually less than 25 mg/l dissolved solids. It is therefore usually aggressive to water distribution systems and must either be blended with brackish water if available or otherwise chemically conditioned if the product is used for water supply.

5.4 Dual purpose desalination-power generation plants

At thermal power plants steam is generated and expanded to drive turbines which in turn drive power generators. The exhaust steam from the turbine is condensed in a condensor and reused as boiler feed. The waste heat in the exhaust steam may, however, be used to evaporate water in a distillation plant. Plants of this nature where steam is extracted from an extraction turbine or obtained from a back pressure turbine (without the last low pressure stages) are referred to as dual-purpose or co-generation plants. The advantage of this type of plant is that the energy required to produce electricity and desalinated water is drastically reduced as compared to two separate plants. The main disadvantage is that power generation and water production becomes interdependent and if either does not operate the other has to shut down. Operation becomes more complicated and stand-by equipment has to be installed.

There are practical limits to the lowest pressure at which the steam can be extracted from the turbine. At low pressures the specific volume of steam can be prohibitively large. Systems such as the waste heat distillation concept in which it is proposed to use waste steam from the turbine house for desalination of effluents suffer from this constraint.

5.5 Application of distillation processes

The main application of distillation processes is for the desalination of sea water for municipal and industrial water supplies. Multi-stage flash had the major share in installed desalination capacity in June 1980 viz 67% compared to 4% for thin film vertical tube, 1,1% for thin film horizontal tube and 1,6% for vapour compression, 20% for reverse osmosis and 3,8% for electrodialysis. (Total installed capacity $7274 \times 10^6 m^3/d$) (Techno-Economic Services 1981). Because the energy consumption in distillation is independent of water quality there is very little cost difference between the production of fresh water from seawater or from brackish water. There is, however, a marked difference in production cost for membrane processes and since membrane processes have been commercialized for large scale applications distillation processes have been limited almost exclusively to seawater desalination and a small number of specialized applications.

Multistage flash is almost exclusively (98%) used to desalinate seawater while multiple effect processes are used for both sea and brackish waters with new plants almost exclusively for sea water.

A specialized application of vapour compression is the vertical tube seeded slurry application for the desalination of wastewaters. A total of thirteen plants are in operation in the USA with a combined installed capacity of 28250 m^3/d. A vapour compression plant of this type is at present being installed at SASOL and should be operational during the second half of 1983.

A plant operating on the same principle but employing horizontal tubes have been commissioned recently in South Africa in New Castle. It is the first of its kind to be installed and no previous operating experience is available.

Falling-film evaporators recover chemicals efficiently

T. M. Fosberg
Resources Conservation Co., P.O. Box 3766, Seattle, Wash. 98124

H. L. Claussen
Crown Zellerbach Corp., Seattle, Wash. 98108

Falling-film evaporators provide stable operation at low heat-transfer values with high heat-transfer rates. These features permit more energy-efficient pulp liquor evaporation than can be achieved with other types of evaporators. With falling-film evaporation, it is possible to select either a vapor compression system or a system having eight or more effects (or a combination of the two), depending on capital and energy cost trades and the mill's energy balance. A vapor-compression, vertical-tube, falling-film evaporator that concentrates both kraft and sweetened semichemical liquors to 50% has been providing significant energy savings and operational benefits to a containerboard mill since this evaporator began operating in Feb. 1981.

KEYWORDS: Energy • Recovery • Evaporators

Falling-film evaporation permits energy-efficient evaporator configurations because it is able to operate stably at low heat-transfer temperature differentials (ΔT) between the condensing vapor and liquor temperatures and with high heat-transfer coefficients. These features make possible the design of multiple-effect systems capable of many more effects than are possible with other evaporator types. For example, up to 14 falling-film effects are feasible for kraft liquor evaporation to 50%, whereas with rising-film evaporators, unstable operation results at the lower ΔT values associated with more than six effects.

Low-ΔT capability also permits energy-efficient vapor compression systems, even for concentrated liquors having high boiling-point rises (BPR), such as kraft liquor. The high heat-transfer coefficients keep falling-film evaporators economically sized at the low ΔT values. Effective mechanical recirculation of the liquor over heat-transfer surfaces, now possible with a new patented distributor, is the feature that permits vertical-tube, falling-film evaporators to operate stably at low ΔT values.

How falling-film evaporation works

The principal parts of a falling-film evaporator are the heating element, vapor body, a pump to circulate liquor through the heating element, and an effective distribution system that uniformly films the liquor onto the heating surface. A typical, vertical-tube, falling-film evaporator body is shown in Fig. 1

1. Vertical-tube, falling-film evaporator body.

2. Mill steam balance.

3. Semichemical, falling-film, vapor-compression evaporator.

Liquor is continuously recirculated within the evaporator from the lower vapor body to the upper liquor box. Flow is maintained with a high-capacity recirculation pump. Complete wetting of the heat transfer surfaces is a key requirement, met by liquid distributors installed in each heat-transfer tube of the heating element. These distributors are inserted in the upper tube sheet and are held in the tube by friction. Liquid flow is directed through holes in the top of each distributor, forming a uniform thin film that completely wets the inside surfaces of the heat-transfer tube. A head of recirculating liquid several inches high is maintained above the distributors to provide the desired flow through each tube. The high liquor-recirculation rate minimizes fouling by eliminating dry spots and limiting concentration increases across the heat-transfer surfaces to only 2% or 3%.

Liquor evaporating in the heat-transfer tubes produces vapor that flows to the vapor body along with the recirculating liquor. As it flows through the vapor body and out of the evaporator, the vapor is subjected to scrubbing and centrifugal and gravitational forces to remove entrained droplets. Each vapor body can be fitted with entrainment separators to achieve a higher condensate quality if needed. Shell-side venting removes noncondensibles and, when required, reduces biological oxygen demand (BOD) and total reduced sulfur (TRS) levels in the condensate.

Evaporator selection—a case study

The falling-film, vapor-compression evaporator was an integral part of a multimillion dollar modernization that makes a containerboard mill 70% self-sufficient in energy by using renewable sources. This modernization also reduced labor requirements by 35%. Two new Kamyr digesters produce pulp for five paper machines rated at 1,034 machine-dry metric tons/day of linerboard and 417 machine-dry metric tons/day of corrugating medium.

Pine wood is pulped in a continuous two-vessel Kamyr kraft digester. Its design capacity is 1,179 air-dry metric tons/day at a yield of 54.5%. A single-vessel semichemical Kamyr digester is used to process mixed hardwoods. The design calls for use of kraft mill green liquor to pulp to a yield of 76% at an anticipated chemical charge of 8% total alkali, both based on oven-dry wood. Blow-line refining is required at this high yield. Conventional washing is incorporated into the semichemical pulping line. Spent liquor is designed to be about 7% solids. Use of green liquor combined with wood acids from the hardwoods results in a spent semichemical liquor with reduced pH and a high carbonate content when compared with kraft.

In addition to the new evaporators, spent liquor is concentrated in 4 sets of conventional rising-film, multiple-effect evaporators which use 445 kPa steam at an economy ranging from 4 to 5. This provides a use for turbine extraction and other lower pressure steam. While kraft liquors are normally handled by these evaporators, a high-carbonate, low-pH spent green liquor would quickly foul and corrode the existing rising-film evaporators, so the latter are restricted to use on kraft liquors. They produce a liquor containing 48–50% solids by weight. This liquor is fed directly to oxidation or is used to sweeten the semichemical liquor.

Steam generation is provided by 7 boilers burning waste liquor, heavy oil, natural gas, and/or wood waste. Generation pressures are 5,965 and 3,205 kPa. Two turbine generators contribute to the mill's electrical power. Both turbines use steam at 5,965 kPa and extract at 1,135 kPa. One turbine is noncondensing and exhausts to the 445-kPa header; the other acts as a condensing turbine when the mill's low-pressure steam requirements are below the production indicated by power demands on the turbines. Two of the paper machines are driven by 3,205-kPa turbines exhausting to the 1,135-kPa header.

In applying the requirements of the vapor compression evaporator to the mill's energy balance, it was determined that adequate minimum-cost, shaft-turning power would be available for the compressor. The mill was found to have a low-pressure steam consumption which made electrical generation possible with little condensing turbine operation. This was important since steam turbines operating in the condensing mode would use far more energy than when operating in the noncondensing mode.

Future plans include installation of a new steam-saving, eight-effect, falling-film evaporator for kraft liquor to replace the older evaporators, so extraction steam consumption was checked on that basis. The steam balance for this condition is given in Fig. 2. The turbines are expected to operate on minimum condensing load while taking full advantage of the vapor compression evaporator.

Semichemical evaporator design

The mill required an evaporator system to concentrate 7% semichemical liquor to 50% solids at an evaporative capacity of 80,740 kg/hr (178,000 lb/hr). The two-stage, vertical-tube, falling-film, vapor compression evaporator system, shown schematically in Fig. 3, meets these requirements.

The weak semichemical liquor is first sweetened with caustic and heavy kraft liquor as required to minimize both the fouling and the release of noncondensible gases. The blended liquor is filtered through a 100-mesh, rotary gravity filter to remove fiber, which is returned to the mill. The feed is then heated in a plate-type heat exchanger using evaporator condensate prior to entering the first evaporator stage. The blended semichemical and kraft liquor is concentrated to about 38% in the first stage. Concentrated liquor from the first stage is fed to the second-stage evaporator body where the final product concentration of 50% is attained. Each evaporator body contains 5.1-cm-diameter heat transfer tubes 10.5 m long. Liquor recirculation in each body is accomplished with 150-kW centrifugal pumps.

The vapor formed in each body flows out through mesh pad entrainment separators and then to a single-stage, centrifugal compressor where it is compressed from near-atmospheric pressure to about 150 kPa. The mesh pad entrainment separators were selected to protect the compressor from carryover. A small amount of vapor is bypassed around the compressor to obtain about 5°C of superheat at the compressor inlet. The compressor is driven with a 3000-kW electric motor.

The compressed vapor is condensed on the shell side of the tubes in the heating element, where the full heat of vaporization of 625 kW·hr/1000 kg is recovered for an electrical energy input equivalent to only about 39 kW·hr/1000 kg evaporated. Condensate flows to a tank and then is pumped out of the system through the feed heat exchanger. Noncondensible gases are collected in a vent tube extending the full length of each heating element at the centerline, and flow with the condensate to the condensate tank. The vent vapors are condensed and the noncondensible gases disposed of in the recovery furnace.

The input to the evaporator system is fed at 93°C. Discharges consist of product at 107°C, condensate at 95°C, and vent gases at 111°C.

Provisions are made for boilout of the evaporator system with warm mill water as required. The entrainment separators are washed on the inlet side on a 6-hr cycle during operation. Continuous washing of the entrainment separators on both the inlet and outlet sides occurs during evaporator boilout. The heat exchanger is kept clean by switching the feed and condensate flows.

Controls are provided for automatic system operation. Feed flow to each evaporator body is controlled by liquid level in the vapor bodies. Product concentration is maintained at a preset point by a density controller on the discharge line. Condensate flow is regulated by level control on the condensate tank. Operating pressure is maintained in the evaporator bodies by controlling the vent rate. The desired evaporative capacity is established by manual adjustment of the compressor inlet guide vanes.

Materials in contact with liquor streams are principally 304 stainless steel. Vapor ducts and the shell of the heating element external to the vapor bodies are carbon steel. The compressor casing and inlet nozzle are cast iron with the rotating assembly 17-4/15-5 PH stainless steel.

Operating results

The system is operated with electrical energy. No makeup steam is required at design feed temperatures. Energy input is through the electric motor drives on the vapor compressor, recirculation pumps, feed pump, and condensate pump. The energy requirement is about 39 kW·hr/1000 kg evaporated. Based on \$0.04/kW·hr power, \$11/1000 kg steam, and 64,600 kg/hr average evaporation, the vapor compression evaporator provides a yearly energy savings to the mill of about \$700,000 over what would have been provided by a five-effect alternative operating at a steam economy of four.

The semichemical, vapor compression, falling-film evaporator provides the mill with operating flexibility. The evaporator system can be brought on line or returned to a hot standby condition in a matter of minutes. Once on line, capacity can be changed quickly, depending upon mill requirements, from full load to as much as 50% turndown. This ease of operation has led the mill to use the semichemical evaporator for as much as 3MW of electrical load trimming. Flexibility is seen in the demonstrated ability to handle a semichemical feed, a straight kraft feed or as a blend as the need arises. The ability to produce a product at a constant, predetermined concentration has been of distinct advantage to the mill. The system normally produces a 50% product but has operated in excess of 60% without any problem.

Foaming has occurred when feed and evaporator concentrations were low. Complete control has been achieved by filling the evaporators with heavy kraft liquor on startup and then keeping the semichemical feed sweetened to design levels.

The evaporator shows no evidence of fouling during operation, making a regular boilout cycle unnecessary. Rather, the system is boiled out on an infrequent basis, usually only when it is scheduled down during periods of low liquor supply. This is compared with the existing rising-film units which must be boiled out on a regular basis.

The condensate produced by the evaporator is of high quality, containing less than 1 ppm sodium measured as Na_2O. This condensate is returned to the

4. Multiple-effect, falling-film evaporator.

mill at approximately 95°C for use in the brown-stock washers.

Multiple-effect, falling-film evaporators

Exceptional steam economy can be obtained from falling-film evaporators with eight or more effects. In some cases, it may be practical to replace inefficient evaporators with a new falling-film, multiple-effect system and pay for the installation out of energy savings. The number of effects are selected to match the mill's specific energy balance requirements. Falling-film, multiple-effects have been proven in commercial seawater desalination applications where up to 17 effects are in use.

A typical falling-film, multiple-effect evaporator system is shown in Fig. 4. This schematic is for an energy-efficient, eight-effect system designed to concentrate weak kraft (13–16% solids) to 50–65% solids. Provisions are shown for soap skimming and segregation of foul condensate. Operating advantages include control of product concentration to a preset point by a density controller and turndown to 25% of full load. Steam economies between 7 and 8 are possible with a system of this type.

Conclusion

Falling-film technology permits the use of both multiple-effect and vapor-compression energy-saving evaporator systems. The semichemical, falling-film vapor-compression evaporator at the Crown Zellerbach Bogalusa mill provides significant energy savings. Additional advantages include the ability to handle a variety of liquors, low fouling, ease of operation, positive control of product concentration, and production of a high-quality condensate. Because of the unique energy-saving features, falling-film evaporation is expected to be the principal type of evaporator used at modern pulp mills.

Plant Energy Conservation:

Energy Conservation By Vapor Compression Evaporation

Vapor compression provides lower energy consumption and operating costs than comparable multi-effect evaporators.

A. H. Beesley and R. D. Rhinesmith
Aqua-Chem, Inc., Milwaukee, Wis. 53201

Vapor compression is a proven means to significantly reduce energy required for evaporation. Vapor compression evaporation has seen rapid growth in North America in the past two decades, especially for pulping liquors, dairy products, and sweeteners, but many engineers are not familiar with its application.

The first vapor compression evaporators using mechanical compressors were built in Europe about one hundred years ago. Since that time, thousands of mechanical vapor compression evaporators have been put into service around the world for desalting seawater and brackish water; several hundred evaporators have been installed in the chemical process industries to concentrate solutions ranging from inorganic chemicals to temperature-sensitive food products. The primary advantage of mechanical vapor compression evaporation over conventional single- or multi-effect arrangements is far lower energy consumption. The rapidly rising prices of oil and other energy sources in the past six years have been an increasing incentive to investigate vapor compression evaporation as a means of reducing energy usage and energy's contribution to product costs.

Operating principles

In a single-effect evaporator, Figure 1, heat released by condensing steam is transferred across a heat exchange surface to an aqueous solution which is boiling at a lower temperature than the condensing steam. The solution absorbs heat and part of the water in the solution vaporizes causing the remaining solution to become richer in solute. The water vapor flows to a barometric or surface condenser where it condenses by releasing its latent heat to cooling water at a lower temperature. The finite temperature differences between the steam, the boiling liquid, and the condenser are the driving forces required so that heat transfer surface areas can be less than infinite. Practically all of the heat removed from the condensing steam (which had been generated initially by burning fuel) is rejected to cooling water and often is dissipated to the environment without being of further use.

The water vapor which flows to the condenser in a single-effect evaporator is at a lower temperature and pressure than the heating steam, but has almost as much enthalpy. Instead of releasing its latent heat to cooling water, the water vapor may be used as heating steam in another evaporator effect operating at a lower temperature and pressure than the first effect.

In a similar manner, additional effects may be added, Figure 2, each effect generating additional vapor which may be used to heat a lower temperature effect. The vapor generated in the lowest temperature effect finally is condensed by releasing its latent heat to cooling water in a condenser. The economy of a single- or multi-effect evaporator may be expressed as the ratio of kilograms of total evaporation to kilograms of heating steam.

The number of effects, and thus the economy, is limited by the total temperature difference (ΔT) between the saturation temperature of the heating steam (or other heat source) and the temperature of the cooling water (or other heat sink). The available temperature difference may also be constrained by temperature sensitivity of the solution to be evaporated. The total temperature difference, less any losses, becomes allocated between effects in proportion to their resistance to heat transfer, the effects being thermal resistances in series.

Heat transfer surface area for each effect is inversely proportional to the net temperature difference available for that effect. Increasing the number of effects reduces the ΔT and evaporation duty per effect which increases the total area of the evaporator in rough proportion to the number of effects.

The temperature difference available to each effect is reduced by boiling point evaluation and by the loss in vapor saturation temperature due to pressure drop. The boiling point elevation (BPE) of a solution is the increase in boiling point of the solution compared to the boiling point of pure water at the same pressure. The boiling point elevation

Figure 1. Single-effect evaporator.

0360-7275/80/3417-0957 $01.00 © 1980 AIChE

Figure 2. Multi-effect evaporator.

depends on the nature of the solute and increases with increasing solute concentration. In a multi-effect evaporator, the boiling point elevation and vapor pressure drop losses for all the effects must be summed and subtracted from the overall temperature difference between heat source and sink to determine the net driving force available for heat transfer.

A vapor compression evaporator system, Figure 3, is similar to a conventional single-effect evaporator, except the vapor released from the boiling solution is compressed in a mechanical compressor. Compression raises the pressure and saturation temperature of the vapor so that it may be returned to the evaporator steam chest to be used as heating steam. The latent heat of the vapor is used to evaporate more water instead of being rejected to cooling water.

The compressor adds energy to the vapor to raise the saturation temperature of the vapor above the boiling temperature of the solution by whatever net temperature difference is desired. The compressor is not completely efficient, having small losses due to mechanical friction, and larger losses due to nonisentropic compression. The additional energy required because of nonisentropic compression is not lost from the evaporator system, however, and serves to superheat the compressed vapor. The compression energy added to the vapor is of the same magnitude as energy required to raise feed to the boiling point and make up for radiation and venting losses. By exchanging heat between the condensed vapors (distillate) and the product with the feed, it is usually possible to operate with little or no make-up heat in addition to the energy necessary to drive the compressor.

Compressor power is proportional to the increase in saturation temperature (ΔT) produced by the compressor. The evaporator designer must trade off compressor power consumption vs. heat transfer surface area.

Selecting the most economical method

Selecting the lowest cost method of evaporation requires knowledge of the costs of energy, capital, operating labor, and spare parts and maintenance over the life of the evaporator. Energy and capital costs dominate and show the greatest variance among types of evaporators, and can be traded off to optimize the type of evaporator selected.

It is often difficult to assign true costs to energy sources. For example, a single- or multi-effect evaporator may be designed to use a source of low-grade heat which would have no other use, such as hot water, flash steam, or turbine exhaust steam. A vapor compressor might be driven by a steam turbine which acts as a reducing valve to provide low pressure steam already needed elsewhere in a plant. Sometimes a costly piece of equipment such as a boiler or electrical substation has to be installed to provide energy for a new evaporation installation. Each case must be considered individually and most equipment suppliers are willing to help investigate the various options.

Figure 3. Vapor compression evaporator.

Figure 4. Energy consumption of vapor compression evaporation.

With those considerations in mind, information is provided to compare energy usage and costs of typical vapor compression and multi-effect evaporators. Figure 4 shows compressor power consumption vs. compressor ΔT. Compressor ΔT is the sum of boiling point elevation, vapor saturation temperature losses due to pressure drop, and net ΔT across the evaporator. If the solution boiling point elevation is too high, compressor power consumption will be prohibitively expensive.

Since boiling point elevation increases with solution concentration, it is often economical to use a vapor compression evaporator to remove part of the water from a solution and reach an intermediate concentration which has a moderate boiling point elevation. Final concentration can then be reached in a single- or multi-effect evaporator. Figure 4 does not include driver efficiency, and is based on a 105-kPa (absolute) evaporator shell pressure. Power requirements change slightly at different pressures.

Factors affecting costs

Vapor compression evaporators in process plants are usually powered by electric motors or steam turbines. Figure 5 shows energy costs for evaporation of 1000 kg of water by a motor-driven vapor compression evaporator. Energy consumption of a multi-effect evaporator may be estimated by using an economy of 0.85 per effect. For example, a three-effect evaporator will evaporate $3 \times 0.85 = 2.55$ kg of water for every kg of steam used. Figure 5 shows that in many cases energy costs for a vapor compression evaporator will be far lower than for a multi-effect evaporator.

Capital costs for vapor compression systems are usually higher than for multi-effect systems, because they are usually designed for a lower ΔT across the evaporator than a multi-effect. Thus, the heat transfer surface area must be greater. In addition, the compressor and driver must be purchased. In some cases a multi-effect evaporator system with more than five or six effects is more expensive than a vapor compression system of the same capacity. Equipment costs are affected by such variables as feed properties, materials of construction, available energy supply, and required scope of supply. It is recommended that manufacturers be consulted for cost information for specific cases.

To understand in what cases vapor compression evaporation may be used successfully and economically, it is necessary to examine some of the factors and limitations that influence the design of vapor compression systems.

Equipment selection

Two types of compressors have been used most often in recent years, positive displacement and single-stage centrifugal machines; each has advantages for certain applications.

Positive displacement compressors, such as rotary lobe or screw type, pump a relatively constant volume of vapor against whatever back pressure (resistance to heat transfer) is developed by the evaporator. Rotary lobe compressors are used for compression ratios (the ratio of discharge pressure to inlet pressure) up to about 2.0, the compression ratio being limited by mechanical and thermal distortion of small clearances inside the machine. Sometimes water must be injected into the compressor casing to reduce the superheat of the discharge vapor to limit thermal distortion. The efficiency of positive displacement compressors will be between 60 and 75%.

The maximum inlet capacity of a single-stage rotary lobe compressor is about 11.6 m^3/s, which is equivalent to 35,400 kg/hr of vapor at atmospheric pressure. Since a positive displacement compressor pumps against whatever resistance is developed by the evaporator, discharge pressure

Figure 5. Energy cost for motor-driven vapor compression evaporator.

will increase and evaporation rate will remain relatively constant as the evaporator becomes fouled. Evaporator capacity may be varied when using positive displacement compressors by: 1) using a variable speed driver, 2) using multiple compressors in parallel, or 3) varying evaporator shell pressure to change vapor specific volume.

Centrifugal compressors are commonly used to compress larger volumes of vapor at lower compression ratios than can be handled by positive displacement machines. Centrifugal compressors have inlet capacities ranging from about 0.07 m^3/s to 94 m^3/s, equivalent to 303,000 kg/hr of vapor at atmospheric pressure. The maximum compression ratio of a single-stage centrifugal compressor is about 1.7 for inlet volumes to 94 m^3/s. The compression ratio is limited by rotor dynamics, gearing, and impeller strength considerations.

One manufacturer (Turbonetics) operates successfully at higher speeds by using high-strength impeller materials, integral gearing, and operation above first critical speed to achieve compression ratios up to 2.0 with a maximum inlet capacity of 29 m^3/s. Higher compression ratios may be obtained either by operating two single-stage machines in series or by using a multi-stage compressor. However, using two single-stage compressors in series is much less expen-

Figure 6. Compressor T vs. inlet saturation temperature for 1.5 compression ratio.

Photo courtesy Allis-Chalmers

Figure 7. Inlet guide vanes.

sive than using a multi-stage compressor. Efficiency of centrifugal compressors is approximately 75 to 80%.

Factors influencing design

Selection of compression ratio is a major design decision, since it requires a trade-off of capital cost and energy consumption. Making the proper decision requires knowledge of energy costs and desired payback period. The decision will also be influenced by feed characteristics, materials of construction, type of evaporator, and hours of operation per year.

Evaporator shell pressure also has a strong influence on capital and operating costs. The most desirable shell pressure is slightly above atmospheric. Vacuum operation is used when it is necessary to keep the solution at a low temperature. Vacuum operation has the following disadvantages:

1) The vapor specific volume is greater, requiring larger compressors and vapor piping.

2) Air leaks into the process, increasing noncondensable loading.

3) A vacuum system with its steam, power and cooling water requirements is necessary to remove noncondensables.

4) Vessels must be constructed for vacuum.

5) Lower solution temperature increases viscosity and reduces heat transfer coefficients.

6) The compressor saturation ΔT decreases with decreasing pressure for a given compression ratio, Figure 6.

7) Many of the disadvantages of operating under vacuum may also be present in single- and multi-effect evaporators, and vapor compression operation under vacuum may be the only means of achieving better than single-effect economy for heat sensitive solutions. Operation at pressures well above atmospheric increases the cost of pressure vessels and the higher solution temperature may increase the rates of fouling and corrosion.

Solution boiling point elevation is a major consideration in selecting compression ratio and heat transfer surface area. If too high, it may make vapor compression evaporation uneconomical due to high compressor power consumption or the need for compressors in series. As mentioned earlier, vapor compression evaporation can often be used for the bulk of evaporation duty on a solution with high boiling point elevation by use as a preconcentrator followed by a single- or multi-effect concentrator. For example, if a vapor compression preconcentrator concentrates kraft pulping liquor from 11 to 40% solids followed by a multi-effect concentrator which does the remaining evaporation to 65% solids, the vapor compression preconcentrator does 87% of the total evaporation duty using far less energy than would a multi-effect evaporator doing the entire job.

System control

The choice of electric motor or steam turbine centrifical compressor driver is determined by the type of energy available in a plant and its cost. Turbine steam rate depends on inlet steam pressure and temperature, exhaust pressure, number of turbine stages, and turbine efficiency. With a turbine driver, evaporation rate may be controlled by varying compressor speed, making sure that turbine and compressor critical speeds do not fall in the evaporation range of interest.

Electric motor and gear drives are less expensive than steam turbines but are not suited for compressor speed control. Instead, evaporator capacity may be controlled by use of inlet guide vanes or a butterfly valve in the inlet to the compressor. The butterfly valve creates a pressure drop and lowers inlet pressure to the compressor. The compressor maintains a constant compression ratio so discharge pressure is also lower. The net ΔT to the evaporator is then lower and evaporation rate decreases.

Inlet guide vanes, which are more expensive than an inlet butterfly valve, operate by causing a prerotation to the vapor entering the impeller. This varies the compressor flow/pressure rise characteristic and provides a compressor power-saving compared to butterfly valve control. Inlet guide vanes are shown in Figure 7.

Compressor speed control and inlet guide vane control have different abilities to accommodate evaporator fouling and part load capacity. This can be seen by examining plots of ΔT vs. flow for the compressor and evaporator together, Figures 8 and 9.

Figure 8 shows use of inlet guide vanes for capacity

Figure 8. Performance curve of vapor compression evaporator with inlet guide vane control.

Figure 9. Performance curve of vapor compression evaporator with speed control.

control. The evaporator curves are a series of straight lines showing that capacity varies linearly with ΔT. The lines have different slopes corresponding to different amounts of fouling (percentage of clean heat transfer coefficient). The compressor curves, each for a different inlet guide vane setting, show that compressor ΔT decreases with increasing flow rate. The intersection of the proper evaporator line with the proper compressor curve is the system operating point. The dashed line marking the left end of the compressor curves is the surge line. Compressor operation to the left of the surge line is unstable, with oscillation of inlet flow. If surging becomes violent or prolonged, the compressor will be damaged.

Figure 9 shows use of speed control. Compressor curves are shown at various speeds. It can be seen that inlet guide vane control allows greater capacity turndown and allowance for evaporator fouling before the surge condition is reached.

Reliability and protection

Large centrifugal compressors have proven to be highly reliable in chemical process evaporator installations. Excessive carry-over from the evaporator and improper matching of compressor and evaporator have been the cause of most operational problems.

It is strongly recommended that a single party take system responsibility for engineering the interfaces between the evaporator, compressor, and driver. Failure to do so has caused some expensive problems. The evaporator manufacturer should be provided with samples of representative feed, because of the influence of feed characteristics on heat transfer coefficient. If the solution is one that foals or foams, pilot testing should be undertaken before the evaporator is designed.

Several actions are recommended to maximize compressor reliability:

1. Minimize entrainment in the vapor by using suitable entrainment separators.

2. Recycle a portion of the superheated compressor discharge vapor to the inlet to dry any remaining entrainment. Water droplets can erode the compressor impeller.

3. Monitor solids content in the distillate. Solids in the vapor may build up on the impeller and break off in pieces to cause imbalance.

4. Examine the impeller periodically through a sight glass in the inlet pipe. Check for evidence of deposits or erosion. The impeller can be checked while running by using a strobe light.

5. Install vibration and temperature monitors on compressor, driver, and gear bearings to warn of imbalance or excessive wear. Automatic shutdown alarms will avoid catastrophic failures. Do not allow operators to override alarms without determining the cause of abnormal vibration or temperature.

6. Open compressor casing drains during shutdowns and use a forced air dryer to keep the compressor dry to avoid corrosion.

Good operator training is of great importance as is a program of regular inspection and operating data collection and review.

In conclusion

The main advantage of vapor compression evaporation is significantly lower energy consumption than single- or multi-effect evaporation in most applications. The vapor compressor may be driven by an electric motor, so evaporation can be used (to reduce the volume of a waste stream, for example) in plants or locations having little or no steam supply. Vapor compression is a means of achieving better than multi-effect economy when evaporating solutions which do not permit use of multi-effects because of sensitivity to high temperatures.

Vapor compression evaporators have no final condenser. Thus, they require little or no cooling water. A vapor compression evaporator may require less space than a multi-effect evaporator of the same capacity; in smaller sizes can be packaged and skid-mounted to reduce installation expenses. In some cases, a vapor compression evaporator can have a lower capital cost than a multi-effect evaporator with many effects.

Vapor compression evaporators are being used in new facilities and to provide added capacity or improved efficiency in existing facilities, they are frequently being used with an existing multi-effect evaporator. To determine the lowest cost method of evaporation, each application must be considered separately based on evaluation of feed characteristics, cost and type of energy sources, possible use of existing evaporators, overall plant energy balance, and return on investment criteria. It is recommended that one party take responsibility for engineering the interfaces between evaporator, compressor and driver.

Vapor compression has proven to be a very reliable method of achieving low energy evaporation when properly engineered and operated. ■

A. H. Beesley, application engineer Aqua-Chem, Inc., earned his B.S. degree in mechanical engineering and biomedical engineering and a M. Eng. degree in biomedical engineering at Rensselaer Polytechnic Institute. A registered professional engineer in Wisconsin, his responsibilities with the Process Systems group include design of evaporators, distillation, and stripping systems.

Gentlemen:

Thank you for your letter of November 19.

Signal Swenson licensee Process Plant (Pty.) Ltd. has supplied to Rustenburg Refiners a metallurgical brine evaporator, which is a mechanical vapor recompression unit on sulfate brine. Swenson expertise lies in the custom design of evaporators, crystallizers and dryers, and we would welcome the opportunity of working on any specific project you may have in mind.

Yours very truly,

SIGNAL SWENSON DIVISION

SWENSON EXPERTISE

— from testing to completion

Swenson engineering expertise is known throughout the world in the areas of evaporation, crystallization and drying. This reputation began in the 1880's when Magnus Swenson built his first evaporator. And it has grown ever since, as Swenson equipment has performed as specified for the worldwide chemical process industries.

To these process industries, Swenson provides a single, responsible source for testing, engineering, fabricating and installing the complete system.

Analysis of individual customer requirements is made in the Swenson Test Center where products are thoroughly tested to determine the feasibility of concentrating, crystallizing and drying. With the Swenson expertise in these areas and the extensive testing equipment in the research center, the results of these analyses indicate which process is best suited for each individual application.

Once the process has been determined, Swenson engineers the equipment and carries the job through to the completed, operating installation.

SWENSON CRYSTALLIZERS

— for a wide variety of applications

A wide range of general and special purpose crystallizers are designed and manufactured by Swenson for the specific needs of the chemical process industries.

Among the most popular of these are the following types:

Forced-circulation crystallizers are well suited for applications where high rates of evaporation are required, where there are scaling compounds, where crystallization is achieved in inverted solubility solutions, or where the solution has a relatively high viscosity.

Draft tube baffle crystallizers are preferred where excess nucleation makes it difficult to achieve a crystal size in the range of 10 to 30 mesh. This growth-type crystallizer is noted for long operating cycles and stable crystal size, regardless of change in capacity.

Surface-cooled crystallizers are utilized at temperatures below which it is not economically feasible to use vacuum equipment or with solutions having very high boiling point elevations.

More detailed descriptions of these and other types of crystallizers are included in current Swenson crystallizer literature.

Mechanical recompression crystallizer

SWENSON EVAPORATORS

— a choice of four types

Swenson designs and manufactures four basic types of evaporators. The first two are used for concentrating solutions where no precipitates are formed. The other two are used for salting and scaling applications.

Long-tube vertical (LTV) rising-film evaporators are commonly used for concentrating many non-salting liquors. **Long-tube vertical (LTV) falling-film evaporators** are preferred for liquors requiring evaporation at extremely low ΔT's and for critically heat-sensitive liquors. Both types provide maximum evaporative performance for the least capital investment.

Forced-circulation evaporators, usually with submerged inlets, are the most desirable choice for applications where precipitates are formed during evaporation.

Calandria, or short tube, evaporators can handle both salting and scaling applications as well as those where no precipitates are formed.

For more specific information, send for current Swenson evaporator literature.

SWENSON DRYERS

— designs for every drying need

Several types of dryers are produced by Swenson to meet virtually any drying requirement.

Spray dryers suitable for either parallel, reverse or mixed-flow operation, dry liquids or slurry.

Flash dryers handle a variety of materials, drying the product in a hot gas stream which pneumatically conveys the material through the body of the dryer.

Fluid bed dryers are available for both open and closed cycle operation.

Steam tube dryers are designed to transfer heat indirectly through the tube wall to the material being dried.

Rotary dryers are designed with parallel current or counter-current operation to suit the specific requirement of the material being processed.

A Swenson bulletin, SW-300, describes each of these dryer types in greater detail.

Dear Hans

Thank you for your letter of 28 March. We have noted your new address. The IDE process and equipment is handled by one of IDE's own staff - Daniel Hoffman - Israel Desalination Engineering Ltd, P.O. Box 450488, Miami, Florida 33145.

I also enclose a black and white photograph of the Aiprene units which photograph is currently in IDE's new brochure - also enclosed. I hope you find them useful.

Sincerely

P.J. WOOLLAM

Brine Concentrator

The Aquaport Brine Concentrator

For Separation of Pure Water and Soluble Materials

The Aquaport Brine Concentrator (A.B.C.) is an advanced type of evaporator, designed to remove most of the water from aqueous solutions, by concentrating them well above their saturation limits. Custom-engineered for specific applications, or package-designed for a multitude of others, the performance and efficiency of the A.B.C. are far ahead of conventional evaporators.

Less than two decades ago, the unique **I.D.E.** low-temperature evaporator systems became commercially available. Since then, more than 150 of these exceptionally cost effective systems, ranging in unit capacity from 20 to 20.000 cu.m. per day, have been installed all over the world.

During all these years, Research & Development teams at IDE have been expanding, modifying and testing the Aquaport designs for a variety of industrial applications requiring the concentration of effluents by evaporation. The result of their efforts is the **Aquaport Brine Concentrator** for recovery of high quality water and concentration of solubles for disposal or recuperation.

The Aquaport Brine Concentrator provides economical solutions to a variety of material recovery and waste disposal problems, ranging from the treatment and concentration of power plant blow-down to zero discharge of chemical plant effluents, and the retrieval of expensive chemicals from noxious industrial residues.

Suspension is the Solution

Threshold and Seeding Pre-Treatment

The seeding technique developed for the A.B.C. prevents scale formation on heat transfer surfaces. It provides nuclei upon which low-solubility compounds such as calcium carbonate and sulfate, and silica will crystallize or precipitate and remain in suspension rather than adhere to metal surfaces. By encouraging the formation of suspensions, seeding actually raises brine concentration levels far above those prevailing in solutions, even at high temperatures. Moreover, since undissolved solids in suspension do not elevate the boiling point of the liquid in which they are suspended, there is a saving in energy requirements. Additional advantages include elimination of the need for water softeners and acids. This reduces the danger of corrosion and minimizes environmental pollution.

Low Temperature Operation

As demonstrated by many years of trouble free operation, the Aquaport low-temperature evaporation process ensures:

- reduced scale formation
- prevention of hard scale
- virtually no corrosion
- many years of trouble-free service
- high availability (ratio of on-line time to total time)
- widest choice of suitable construction materials for specific applications
- no need for make-up heat
- stable operation
- easy regulation of capacity within a wide range.

High Efficiency, Lower Maintenance Costs

The falling film-horizontal tube arrangement of the A.B.C. is probably the most efficient and cost-effective design available today. It only requires low grade heat sources. Therefore, industrial waste heat can generally provide the system's total energy requirement.

Because of the non-erosive film flow and minimal scale buildup on the tubes, the system is virtually maintenance-free. The relative absence of scale results in unrestricted water flow and the effective scavenging of non-condensible gases (NCG) averts the formation of diffusion barriers.

Another important advantage is that the distillate is never contaminated by brine leakage, since the higher pressure of the vapor on the distilled water side is an effective impediment to brine infiltration.

Low-Cost Energy Source Options

Motive power for the Aquaport Brine Concentrator can be provided by either of two efficient methods:

- electrically-driven Vapor Compression utilizing the heat-pump principle
- low-grade heat, especially waste heat, in Multi-Effect Distillation with or without vapor recompression.

Aquaport systems have the industry's highest economy ratios, i.e., the ratio of end product to energy consumption.

Sound Engineering Principles

Sound engineering principles, reliable manufacturing practices and reputable ancillary equipment enhance the quality and reliability of every A.B.C. The many features incorporated in the A.B.C. are illustrated in the following flow diagram (page 8-9).

Horizontal Tubes, Falling Film, Evaporator Condenser

1. Feed from boilers and cooling towers blow downs, dilute process solutions and industrial effluents
2. Chemical Dosing System: chemical additives harmlessly precipitate scale-forming chemicals and keep them suspended in the brine, virtually eliminating scale deposits on heat transfer surfaces
3. Feed Heat Exchanger
4. Air removal auxiliary condenser
5. Recirculation pump
6. Brine spraying system
7. Low cost high durability heat transfer surfaces
8. Droplet separator minimizes brine carrying over into water vapor
9. Vapor compression system
10. Compressed vapor condenses inside the horizontal heat transfer tubes
11. Distillate Chamber
12. Distillate Pump
13. High quality water outlet
14. Saturated brine containing suspended solids collects in chamber for recycle or discharge
15. Brine pump
16. Hydrocyclone separates brine into clear stream and slurry
17. Part of the slurry is returned to the unit to ensure solid concentration
18. Out going clear brine stream
19. Out going concentrated slurry stream
20. NCG removal vacuum system

Solving Problems of Economy and Ecology

The growing awareness, worldwide, of the damage caused by industrial pollution to the environment has prompted many countries to pass legislation designed to conserve natural resources and reduce air and water pollution. The Aquaport Brine Concentrator offers industry a sound solution to many pollution problems, and an economic way to comply with such legislation.
The following are typical examples of the Aquaport solution to pollution problems.

The Pulp and Paper Industry

Since pulp and paper mills are almost always located alongside streams, their untreated effluents can harm vegetation and wildlife along the watercourse. The Aquaport Brine Concentrator helps this essential industry to achieve zero discharge.
The figure below illustrates typical Aquaport treatment of waste from kraft mills.

Suspended, dissolved and biodegradable matter are removed by conventional primary, secondary and tertiary treatment. After the brine has been concentrated in the A.B.C., it is solidified in a crystallizer. The crystallized waste is disposed of harmlessly.

Pulp Mill Effluent Treatment

Electrical Generating Installations

The Aquaport Brine Concentrator can be effectively used for continuous treatment of;

- cooling tower blow-down
- boiler blow-down
- wet scrubber effluents
- ion exchange regeneration wastes

Typical effluents from electric utilities.
As shown above, most power stations provide two sources of waste heat which can be exploited for the concentration process: exhaust heat from turbine back pressure, and hot water returning from the cooling tower. Alternatively, electrical power or low-pressure steam can be used.

The Water Supply Industry

Many countries in dry sub-tropical and equatorial regions have the possibility of utilizing paleo-aquifers and other underground water sources for domestic and agricultural use. In some areas, geothermal water is a potential source of low-cost energy. Both these types of water sources are characterized by excessive hardness salinity, sulfurous smells and other noxious odors, finely suspended insoluble solids, and other factors which render them unusable in their natural condition.

Solution		R.O. + Brine Concentrator	Brine Concentrator	Brine Two stages Concentrator Crystallizer Centrifuge	Brine Concentrator
Output:					
Distilled Water cu.m./day		4,985	4,950	980	1,770
Clear Brine		14	49	—	230
Crystallized Solids		1	1	20	—
Energy Requirements:					
Steam Tons/hr		8.5	16.5	—	—
Power, KWh/cu.m. distillate		3.5	2.5	22	23

Selecting The Right Concentrator

Concentrators can be driven either by a vapour compressor or steam (live or waste). Compressor size limits the vapour compression concentrator to about 3000 ton vapour/day above which multi-effect units must be used. However, when steam is available even small units can use multi-effect configurations. A wide range of concentrators is available to meet specific requirements of any project. The following table is an example for cooling tower blowdown applications.

Capacity Tons of Vapours/	Brine Concentration T.S.	Driving System	Number of Effects	Specific Consumption KW hr. per ton vapours	Specific Consumption Kg. Fuel No. 6 per ton vapours
100-300	10%	Compressor	1	10-18	—
	20%	Compressor	2	16-24	—
	30%	Compressor	2	18-26	—
300-3000	10%	Compressor	1-3	10-16	—
	20%	Compressor	2-4	14-24	—
	30%	Compressor	2-4	16-24	—
1000-6000	10%	Steam	8-14	4	6-7
	20%	Steam	6-12	3.5	7-8
	30%	Steam	4-10	3	8-9

The I.D.E. Approach From F.O.B. to Turnkey

- to solve your effluent disposal problems
- to recover valuable chemicals from aqueous solutions
- to optimize your process economics
- to produce pure distilled water for any need I.D.E. will offer you a broad range of services.

I.D.E. can help you identify your problem, suggest the optimal solution and implement it, undertaking total project responsibility for performance and reliability. From laboratory testing to power source optimization, from F.O.B. supply of components to complete turnkey project implementation (including long-term operation and service insurance if desired) – I.D.E. will solve your problem efficiently, flexibly and economically.

Bulletin 108-9.78
Press Release - September 15 1978

High performance, low temperature IDE Multi-Effect Distillation Plants win in Virgin Islands 3.75 MGD competition

After intense competition with the world's desalination giants, Israel Desalination Engineering Ltd. has been selected to provide three 1.25 million gallon per day sea water desalination plants to the U.S. Virgin Island Water and Power Authority (VIWAPA). Cost effectiveness combined with proven plant performance and reliability gave IDE the edge over others for the plants to be installed next to existing power and desalination stations, two on St. Thomas and one on St. Croix Islands.

The plants are based on IDE's unique Low Temperature, Horizontal-Tube, Falling Film, Aluminum Alloy, Multi-Effect Distillation process which is ideally suited for dual purpose applications requiring steam at only 6 psia, i.e. low grade back pressure steam that has been almost completely expanded in the turbine. For VIWAPA's project, however, 40 psia steam has been made available from existing turbine extraction points. The plants will utilize this steam in a thermo compression cycle to achieve an Economy Ratio in excess of 10:1.

In the future, VIWAPA will consider the feasibility of converting its 35 MW turbine (St. Thomas) to low back pressure operation, thereby making available sufficient steam to produce 6 million GPD of desalinated water with an overall loss of less than 6 MW in power output. In this manner, the energy cost chargeable to the water would be equivalent to only 24 kwh/1000 U.S. gallons.

The IDE supplied plants will operate with a top brine temperature of only 165°F. Harmless polyphosphate scale inhibitors will be used for feed pretreatment in contrast to corrosive sulfuric acid required in older type (MSF) plants.

The IDE multi-effect desalination aluminum alloy design is embodied in the 1 million gallon per day plant in operation in Eilat, Israel since February 1974. The plant, operated by the Mekorot Water Company as a primary water supply to the city of Eilat, has had an on-line demand availability of over 90% since start of commercial operation in May 1974. This single purpose plant has a demonstrated Economy Ratio of over 11:1 with a top brine temperature of only 160°F and simple polyphosphate feed pretreatment.

Additionally, IDE commissioned in January 1977 five similar 500,000 gpd plants on Kish Island in the Persian Gulf. As a result of performance of these plants exceeding specifications, IDE has recently received an order for a sixth unit and a contract to supply five more similar plants for another Persian Gulf installation.

IDE's First In Caribbean, But No Newcomer to Desalination

Althought the Virgin Island contract represents its first project in the Caribbean, IDE is no newcomer to the field of sea water desalination. As a fully owned government company, Israel Desalination Engineering was commissioned in 1961 to find solutions to the long term national water problem. Initial development of freezing processes gave way to development of vapour compression and multi-effect distillation processes operating at low temperatures. Product commercialization on the international market was undertaken in 1967 with the installation of the first of over 100 AQUAPORT vapour compression distillation plants sold to date.

Simultaneously, a succession of MED pilot plants were built leading to the sale and commissioning in 1974 of the first commercial 1 million GPD plant in Eilat and more recently to eleven 500,000 GPD plants in the Persian Gulf area.

Now, IDE is designing and will soon initiate construction of a 10 million GPD dual purpose desalination plant in Ashdod as part of the joint US-Israel governments' program for developing economic, large scale desalination technology. The plant will operate on 5.5 psia back pressure steam from an existing 50 MW power plant and will be the prototype module for the next generation of MED plants up to 100 million GPD to be coupled to conventional and nuclear power plants.

Multi-Effect Distillation
Sea Water Desalination Plant
(1 MGD), Eilat, Israel

the

aquaport®

vapor compression distillation at ambient temperatures

Israel Desalination Engineering (Zarchin Process) Ltd., IDE, is recognized internationally as a leader in the development, engineering and production of advanced desalination systems.

Relying on a nucleus of highly skilled scientists, engineers and technicians, most of whom have been with the company since its establishment in 1958, IDE has maintained steadily one of the highest sales growth rates in the industry.

Behind this remarkable growth lies the fact that all IDE products are unique, based on original, self-developed processes and designs, with distinct advantages and features.

To the cost conscious operator or the profit minded businessman involved in the production of desalinated water these features mean a substantial and real saving of money, lower annual costs, larger profit margins.

The professional engineer will recognize and appreciate the beauty of a simple yet sophisticated design which assures long term trouble-free operation and superior performance.

The Aquaport Ambient Temperature Vapor Compression distillation plants described in this brochure represent IDE's successful solution for small and medium capacity desalination applications.

They are clearly in a class by themselves.

BATEMAN ENGINEERING LTD.

Bringing Water Cost Down

The success of the Aquaports is due to two basic features which distinguish them from other distillation plants.

Ambient temperature operation = dependability

The Aquaports operate at unparalleled low temperatures, 30 to 55°C (85 to 130°F), reducing scaling and corrosion to a minimum. Scaling and corrosion are behind 90 percent of all problems plaguing conventional high temperature distillation plants, which operate at 90 to 120°C (200 to 250°F).

The Aquaports' low temperature operation is the key to long term trouble-free service and to reduction of maintenance and labor costs to negligible proportions. This is particularly critical in small and moderate sized plants where such costs must be charged to relatively low outputs.

Low energy consumption = economy

Energy contributes today 60 to 80 percent of desalinated water cost.

The standard Aquaports' specific energy consumption is only 18.5 kwh/ton (70 kwh/1000 US gal.). This is equivalent to 4 kg fuel per ton (33 lbs/1000 gal) product, where power is derived from an adjoining diesel generator set, or to an Economy Ratio (ER) of 18:1 in steam operated distillation plants. These plants, however are manufactured with ERs of only 4:1 to 8:1 in the capacity range covered by the Aquaports, requiring as much as 10 to 20 kg of fuel per ton product.

With the Low Energy LE series of Aquaports, which require only 12 to 14 kwh/ton (45 to 53 kwh/1000 gal.), this wide margin of economy is increased even further. The LE units' energy consumptions are equivalent to ERs of 30 to 35:1 and to a specific fuel consumption of 2.5 kg fuel/ton product (21 lbs/1000 gal), namely a water to fuel ratio of 400:1.

Other Features

High Quality Water. Normal product purity is better than 10 ppm TDS. Less than 2 ppm TDS possible if required.

Simplicity. Easy to operate and control. Fully automatic, requiring minimum attention. Safety shutdown and alarm system protects unit during unattended operation. Easy personnel training. Reduced labor costs.

Flexibility. Quick startup. Little time lost for heating up. Immediate production. Convenient for intermittent operation. Capacity regulated by simple controller adjustment to meet varying demand rates. Relaxes storage requirements. Allows supply of power to other consumers during peak load hours.

Reliability. Experienced engineering, rugged construction, quality fabrication and proven standard equipment. Each unit is factory assembled and tested to satisfaction before shipment.

Safety. Safe to operate and maintain. No acids, caustics, fire hazardous fuels, hot surfaces or high pressures.

Environmentally Clean. Neat, functional and colorful design. Requires electrical or mechanical power only. No steam plant. No smoke stack. No fumes. No pollution.

Easy Installation. Great savings in erection time and costs. Units are compact and skid mounted. Minimal site preparation and civil works. Few and simple connections. Small sea-water intake system.

Guarantee. Full one year guarantee for all parts and components.

Service. World-wide sales and service organizations.

Typical operating cost breakdown

	Standard AQ-590 Model	Low Energy LE-590 Model
Energy @ 2.5 US¢/kwh	46 US¢/ton	32 US¢/ton
Labor @ 3 US$/man-hr	3	3
Consumables (spare parts and chemicals)	6	6
Total operating costs	55 US¢/ton (2.00 US$/1000 gal)	41 US¢/ton (1.55 US$/1000 gal)

The Ambient Temperature Vapor Compression Distillation Process

Inherently simple and efficient

Vapor Compression Distillation is inherently the most efficient distillation process. It achieves its high efficiency in a simple, single-effect fashion, without the need for a complex design based on a large number of stages or effects, by application of the "heat pump" principle to continuously recycle and keep within the system the latent heat exchanged in the evaporation-condensation process. In this scheme the heat required to evaporate part of the processed feed, which flows on one side of a heat transfer surface, is supplied through the simultaneous condensation of the distillate-producing vapor on the other side of the surface.

The driving force for this heat transfer, plus the energy required to separate the solution and overcome dynamic pressure drop losses and other irreversibilities are provided through the work of a compressor, which acts as the "heat pump", pumping the vapor generated from the solution to the higher pressure-enthalpy level required on the condensing side.

This work, plus a fraction required for liquid pumping, is the only energy consumed by the process. No additional heat is required.

In the Aqueports even this low energy requirement has been reduced to a minimum by adopting a highly efficient falling film, horizontal tube evaporator, which incorporates large heat transfer areas and reduces parasitic pressure drop losses by integrating the compressor within the evaporator. Due to this evaporator design the pumping head of the compressor is equivalent to a total ΔT of only 4°C (7°F) in the standard models and as low as 2.5°C (5°F) in the special LE (Low Energy) models.

The Aqueports are unique also in that the distillation step is carried out at close to ambient temperatures. The ability to operate at such low temperatures is due to the exclusive development by IDE of a novel lightweight, high volumetric flow compressor which is capable of handling the large rarefied volumes typical of low-temperature, low-pressure steam.

Features Due to the Vapor Compression Process

- Low energy requirements, due to "heat pump" principle.
- Simplicity. Plant is a single effect distiller, requiring only a tube heat, a compressor, a feed heat exchanger and pumps.
- Easy operation. Few controllers required to achieve complete automation, allowing long term unattended operation.
- Easy regulation of capacity through one controller adjustment. Power consumption directly proportional to production rate.
- Small saline water supply system, since no cooling water is required. Feed rate is only 2 to 2.5 times product rate. Simple shallow well by sea is sufficient, eliminating expensive civil engineering for jetties, trash racks and filters. Saving in feed pumping power consumption.

Features due to Low Temperature Operation

- Minimum scaling rates. Long term operation (up to 2 years) between scale cleanings. Low consumption of scale removing chemicals.
- Allows use of low cost non-corrosive polyphosphate for feed pretreatment. No acid feed pretreatment required.
- Scale is mostly soft acid-soluble carbonate scale. Operating conditions far removed from saturation curves of problematic calcium sulphate and magnesium hydroxide scales. Descaling is a simple procedure of mild acid recirculation using the plant's own recirculation pump.
- Minimal corrosion rates. Extends lifetimes of all plant materials. Allows use of non exotic materials and epoxy coatings.
- Small feed heat exchangers, since feed must be preheated by only 10 to 30°C (18 to 54°F) rather than by 80 to 100°C (145 to 180°F), as in high temperature vapor compression plants.
- Allows use of corrosion proof, smooth PVC pipes, valves and accessories which would lose rigidity at temperatures above 80°C (180°F).
- Eliminates need for cumbersome and costly plant insulation.
- Eliminates the need for makeup heat to maintain thermal balance.
- Allows quick startups. Little time need be wasted for heating to process temperature.

Features due to Falling Film, Horizontal Tube, Evaporator-Condenser

- Single effect distillation. Simultaneous transfer of latent heat on both sides of heat transfer surface at a constant temperature difference. No loss of effective thermal driving force due to sensible heating of liquid.
- Thin film flow avoids static head suppression of the driving force for evaporation.
- Dominant liquid to liquid heat transfer resistance reduced through film thickness control rather than through turbulent high velocity flow as in forced circulation systems.
- Low liquid flow rates. Small pumping energy requirement.
- Gentle non-erosive film type flow increases material lifetime.
- Non-pressurized brine flow. Vapor and product side pressures always higher than brine side pressures. No contamination of product through brine leakage possible even in case of tube perforation.
- Efficient scavenging of NCG reduces its partial pressure and avoids creation of diffusion barriers.
- Integral compressor design shortens vapor flow path and eliminates cross-section restrictions and unnecessary pressure drops through external piping and valves.
- Large vapor release surfaces. No violent flashing. Reduces brine carryover and demister requirements. Assures high quality product. Lower susceptibility to foaming. No need for anti-foaming additives.

Principles of Operation

The incoming saline feed is pretreated with a minute dose of scale inhibiting additive and passed through a heat exchanger, where the heat in the discharged brine and product streams is recuperated.

This heat is generated in the unit itself, and is a converted form of the mechanical energy supplied to compress and circulate the fluids. Consequently, no separate makeup heat source is needed.

By simple preset of an automatic controller, which regulates heat-exchanger flows, the unit's operating temperature, and hence production rate, may be easily adjusted. These temperatures are always below 55°C (130°F) to minimize scaling and corrosion.

The feed is mixed with recirculated brine and sprayed on the outside of a bundle of horizontal heat transfer tubes, at a rate just sufficient to create thin, continuous liquid films.

A unique centrifugal compressor provides, through its suction, a pressure lower than the equilibrium pressure of the brine. As a result, part of the brine flashes into vapor.

After passing through a demister, to remove droplet carryover, the vapor is compressed and discharged to the inside of the tubes. There it condenses, supplying the latent heat required for the flashing process.

The condensate, which is the salt-free product, and the rejected brine are pumped out, after exchanging heat with the feed.

Non-condensible gases are first concentrated in an auxiliary condenser and then exhausted by means of a rotary vacuum pump, which also serves to create the initial vacuum.

Flow diagram

Falling film evaporative condenser consisting of:

Main vessel: Welded pressure vessel, designed to British and A S M E Standards. Mild steel, coated with six layers of epoxy-resin, with pinhole detection quality control to ensure effective corrosion resistance

Heat transfer tubes: Of special corrosion resistant aluminum alloy suitable for sea water applications

Droplet separator: Stainless-steel wiremesh type demister for efficient elimination of brine carryover, ensuring high product purity with a negligible vapor pressure drop

Brino spray system: Efficient non-clogging, corrosion-proof ebonite spray nozzles

Pumps: Centrifugal low suction head back pulled type to A S M E standards for easy maintenance. Double mechanical seals. Materials and characteristics specified to ensure trouble-free high-efficiency service. Stainless steel casings, impellers and shafts for brine and sea water service

Valves: Diaphragm type to ensure max tightness. Mouth PVC with neoprene diaphragms, totally immune to corrosion

Piping: Mouth PVC clean and smooth, totally immune to corrosion

Feed heat exchangers: Double-pass plate type for efficiency at low cost. Compact and easy to service. Titanium plates. Nitrile rubber gaskets

Air removal condenser: Direct contact type for efficient air extraction of non-condensable gases and concentrate feed deaeration

Pump motors: Totally enclosed fan cooled, to ensure trouble-free outdoor operation

Skid base: A steel frame uniting the main vessel support structure, all pumps, motors, piping and the central instrumentation controls and electricals cabinet

Vacuum pump: High performance rotary piston type

Central controls, instrumentation and electricals panel: Drip-proof cabinet. Easily accessible. Containing complete electrical system, push-button motor starters and controls. A central display of all instruments and controls allows easy supervision of plant operation. Instrumentation and controls connected to an integrated sequence sensitive, safety alarm and shutdown system. All instruments are of high quality and reliability to ensure steady operation with a minimum of supervision

Compression system: Patented lightweight, radial blade centrifugal compressor. Rotor of special low density and fatigue-resistant materials. Stainless-steel shaft. Force-lubricated top quality bearings. Mechanical seal. Simple direct-drive power transmission

The Plant - A Compact and Elegant Design

proven in over 10 years of field operation refined through experience with over 100 units

The Mobile Series up to 100 tons/day

Instant water on a temporary basis

The Mobile Series answers the need for portable desalination plants capable of rapid deployment and immediate production.

The plants are supplied with an auxiliary feed intake system, complete with feed pump, the filter end of which can be inserted into any brackish or polluted water hole or submerged in the sea. Standard flexible feed line length is 15m., but longer lines may be supplied upon request.

Power can be provided from any portable diesel generator set stationed alongside the plant. A 10m long power cable connection is provided as standard equipment.

Typical applications are military logistic support, civil emergency sets for disaster areas, oil drilling and other temporary work camps, nomadic sheep or cattle raising herds, which shift from one water hole and grazing ground to the next.

Where storage capacity is available, one mobile unit can be rotated and operated periodically, serving several small communities spread out over a large area whose small water requirements do not justify installation of a fixed plant with fixed personnel.

Model No.	AQ2500	AQ5000	AQ7500	AQ10000

The Mid-Range Series 100 to 500 tons/day

the classic models

The Mid-Range Aquaports are ideal for serving hotels, tourist development centers, real estate developments, military bases, power stations and moderate size municipalities.

Over the past ten years more Aquaports have been sold in this capacity range than any other distillation plant of comparable size.

Model No.	AQ100	AQ150	AQ200	AQ250	AQ300	AQ350	AQ400	AQ450	AQ500

The Low Energy (LE) Series

lowest energy consumption of any distillation plant

The fourfold increase in fuel price since 1973 has magnified the energy cost component in desalinated water costs and provided an incentive to design plants in which the trade-off point between capital and energy costs is shifted in favor of lower energy consumption.

The LE Series of Aquaports has been developed along this line, incorporating larger heat transfer surfaces and more efficient vapor compressors. They require only 12 to 14 kwh/ton product (45 to 53 kwh/1000 gallons). To gain greater economy, the LE plants are designed to utilize waste heat from the power supply diesel or from any other low grade heat source.

The LE Series is ideal for high fuel cost areas and where continuous operation, i.e. a high annual utilization factor, is foreseen.

Model No.	LE 150	LE 200	LE 250	LE 300	LE 400	LE 500
nominal capacity (tons/day)	150	200	250	300	400	500
saline feed rate (tons/hr)	15	20	25	30	40	50
specific energy consumption (kwh/ton)	14	13	13.5	14	12.5	13
nominal power consumption (kw)	90	110	145	175	210	270
minimum power supply rating (kva)	210	250	300	365	450	560

The Top Range Series 500 to 1000 tons/day

bigger building blocks for larger capacities

The Top Range Aquaport Series has been developed to meet the demand for larger Aquaport units to supply new large-scale regional projects and to replace existing inefficient single purpose MSF distillation plants.

The Top Range Aquaports offer economies of scale and enable meeting multi-thousand tons per day requirements with a battery containing a reasonable number of units.

Scale-up has been achieved without losing the easy handling and installation features of the smaller sized Aquaports. The Top Range Aquaports are, similarly, skid based, packaged units. Dimensions and weights have been kept within internationally accepted limits required to allow ready transport over main thoroughfares.

Model No.	AQ500	AQ600	AQ1000
nominal capacity (tons/day)	500	600	1000
saline feed rate (tons/hr)	60	80	100
specific energy consumption (kwh/ton)	15.5	17	18.5
nominal power consumption (kw)	387	587	770
minimum power supply rating (kva)	600	1190	1560
dimensions (m) L	9.0	9.0	9.0
W	4.5	4.5	5.0

Israel Desalination Engineering has been leading the desalting industry in technological innovations for over 10 years, with its novel, highly reliable, efficient and simple evaporator-condenser. Now, after years of development and testing IDE announces its unique new

BRINE CONCENTRATOR

to recycle or extract valuable chemicals from aqueous solutions, to meet environmental requirements for effluent disposal or to retrieve suspended or dissolved constituents IDE Brine Concentrator is your dependable partner.

DEMONSTRATION OF THE CONCENTRATOR PERFORMANCE

Two test runs are described to demonstrate the concentrator capability

Concentrating Sea Water up to 25% TDS	
Feed to Concentrator	Sea Water 4% TDS No Suspended Solids
Concentrated Brine Outlet	25% TDS about 5% TSS (Total Suspended Solids)
Product	10 ppm TDS

Concentrating Tap Water 1000 PPM up to 30% TS (Total Solids)	
Feed to Concentrator with anlysis	tap water 1000 ppm TDS 100 ppm Ca^{++} 40 ppm Mg^{++} 320 ppm HCO_3 20 ppm HS_2O_3 260 ppm $SO_4^{=}$ 200 ppm Cl_2
pH =	7.5 and No Suspended Solids
Concentrated Brine Outlet	24% TDS 6% TSS 30% TS
Product	10 ppm TDS

Heat Transfer surfaces remain clean after long periods of operation and coefficients of performance are steady and high

HORIZONTAL TUBE BRINE CONCENTRATOR

SELECTING THE RIGHT CONCENTRATOR

Concentrators can be driven either by a vapour compressor or steam (live or waste). Compressor size limits the vapour compression concentrator to about 1000 ton vapour/day above which multi-effect units must be used. However, when steam is available even small units can use multi-effect configurations.

A wide range of concentrators is available to meet specific requirements of any project. The following table is an example for cooling tower blowdown applications.

Capacity Tons of Vapours/day	Brine Concentration T.S.	Driving System	Number of Effects	Specific Consumption KW hr per ton vapours	Specific Consumption Kg fuel No. 6 per ton vapours
100-300	10%	Compressor	1	15—20	—
	20%	Compressor	2	18—24	—
	30%	Compressor	2	20—26	—
300-1000	10%	Compressor	1	14—18	—
	20%	Compressor	2	16—22	—
	30%	Compressor	2	18—25	—
1000-6000	10%	Steam	14	4	7
	20%	Steam	12	3.5	7.5
	30%	Steam	10	3	8

OPERATION OF THE VAPOUR COMPRESSION BRINE CONCENTRATOR

The incoming feed is pretreated with a minute dose of scale crystals-growth modifiers and passed through the product feed heat exchanger, where the discharged product heat is recuperated.

The heat is generated in the unit itself, a converted form of the mechanical energy supplied to compress and circulate the fluids. No separate makeup heat source is needed.

The feed is mixed with recirculated brine and sprayed on the outside of a bundle of horizontal heat transfer elements especially tailored for the purpose of concentrating solutions. The evaporting brine descends in thin films upon the outer face of the tubes, causing condensation to take place inside. The vapors evolving from the brine are drawn through a droplet separator, compressed and discharged into the tubes for condensation. The condensate is a salt-free product, while the concentrated brine is far above the scale saturation limit. The heat transfer surfaces are kept clean due to a unique seeding technique which combines prevention of calcium sulfate and silica together with calcium carbonate scale. No acid treatment to break down the carbonates is needed in the process.

The brine leaving the concentrator is turbid, but by use of a settler and, if necessary, by injection of a coagulant aid, the brine is split into two streams. The main stream is a clear brine while the minor stream is a slurry containing the scale crystals, calcium carbonate, sulfate and silica.

The clear highly concentrated brine solution contains valuable constituents as a by-product of the process. These constituents may be retrieved by crystalization, evaporation or other means, as the case may be.

Non-Condensible Gases are first concentrated in an auxiliary condenser and then exhausted by means of a rotary vacuum pump.

a new concept in multi-effect distillation

at low temperatures

MED

AQUAPORT MED is a completely new development in the field of desalination — a proven process which offers the maximum promise for lowest cost distilled water.

Commercially offered for the first time in 1967, over 130 desalination plants based on the AQUAPORT evaporator-condenser have been installed and operated world-wide. Within a few years after the construction and initial operation in 1974 of the first large-scale, commercial AQUAPORT MED plant — a 3800 ton/day facility in Eilat, Israel — IDE commissioned five 2000 ton/day units on Kish Island in the Persian Gulf. Impressed with their performance, the Iranian Government orderd five more similar plants in 1978.

The same year, following an intense competition with the world's desalination giants, IDE was selected by the U.S. Virgin Islands Water and Power Authority to supply three 4730 ton/day AQUAPORT MED plants for the islands of St Thomas and St. Croix. Excellent cost-effectiveness plus proven performance and reliability gave IDE the edge in the world-wide competition.

Today, IDE is responsible for the design, construction and commissioning of the world's largest MED desalination plant. This 10 MGD plant will operate with exhaust steam from a 50 MW power plant turbine located in Ashdod, Israel. It will produce fresh water from the sea at costs lower then any other type of desalination plant.

More Water for Less Money

In dual purpose, power and water production combination plants, the AQUAPORT MED achieves energy costs lower than those of any other known distillation, reverse osmosis or freezing process for seawater desalination.

AQUAPORT MED has by far the industry's highest Economy Ratios — the weight ratio of distillate produced to

heating steam consumed — of plants operating at maximum brine temperatures below 75 C (167°F). Economy Ratios of 14:1 with 10 ata steam or 9:1 with 0.3 ata "low-grade" steam from a back pressure turbine are available

Proven Reliability

Operating with maximum brine temperatures of less than 75 C (167 F), AQUAPORT MED employs harmless, non-corrosive polyphosphate feed additives which reduce scale and corrosion to a minimum. Dangerous and corrosive acids are not required. Low temperature operation permits extensive use of corrosion proof polypropylene and PVC plastic piping.

Requiring only simple controls, few relatively small pumps, virtually no moving parts and serviceable standard components, few and easily trained workers are needed for plant operation and maintenance.

Inherently Stable and Load Following

Fully automatic, the system is capable of operation at any capacity from 40 to 120% of normal rating purely as a function of steam supply rate. Because of its wide capacity range and unmatched inherent load following characteristics, AQUAPORT MED is the ideal solution for dual purpose, power and water production plants.

Cost Effectiveness

High Economy Ratios, low energy costs, competitive plant prices, minimal personnel requirements and proven on-line availability make AQUAPORT MED the most cost-effective method of desalination, today and in the years ahead.

Aquaport MED: A Better System

Unparalleled Efficiency

[illegible]

Low Temperature Minimum Scale and Corrosion

[illegible]

[illegible]

Low Energy Cost and Heat Source Versatility

[illegible]

Easy Capacity Regulation

[illegible]

Stable Automated Operation

AQUAPORT MED is inherently stable, requiring few controls and minimal operating personnel.

The liquid flow in all the effects is independent of pressure and temperature gradients, and is virtually unaffected by seasonal variations. Production never suffers from the flow irregularities characteristic of other types of plants, such as short-circuiting, liquid flooding, and reduced flow rate due to scaling are completely eliminated in the AQUAPORT MED. Capacity and flexibility for use are dependent only on the number of effects, steam pressure and steam supply rate.

Highest Reliability, Lowest Maintenance

AQUAPORT MED's simple no chemical design and rugged construction promote trouble-free operation and minimal maintenance. All AQUAPORT's are equipped with components of reliable design and highest quality, approved by leading international manufacturers.

[illegible]

The Process

Multi-Effect Distillation is the most practical and least expensive method of producing large quantities of fresh water from the sea. The AQUAPORT MED process is by far the most efficient and cost-effective system of this type. Characterized as Low Temperature, Horizontal Tube, Falling Film Multi-Effect Distillation, AQUAPORT MED — like other systems in the AQUAPORT series — is based on the unique IDE evaporator condenser which uses specially selected aluminum alloy tubes for maximum thermodynamic efficiency and minimum cost.

Heat Recovery and Rejection

A train of identical, interchangeable evaporator condenser effects forms the Heat Recovery Section of AQUAPORT MED. The process delivers up to 14 times more distillate by weight than required motive steam — a most impressive Economy Ratio.

Latent heat given off by the motive steam is re-used in successive effects, with each step taking place at a slightly lower temperature-pressure liquid-vapor equilibrium point. Finally, in the Heat Rejection Condenser, latent heat remaining in the system is rejected by using it to raise the temperature of incoming seawater.

Seawater Feed

Incoming seawater, de-aerated and preheated in the condenser is divided into two flows. One acts as coolant, and eventually returns to the sea, the other becomes feed for the distillation process.

The feed is treated with a harmless polyphosphate additive to inhibit scaling, then fed into the lowest temperature group of Heat Recovery Effects. A spray nozzle system distributes it over the top rows of tubes in each effect. As the feed flows in thin films down each bank of tubes, part of it vaporizes as it absorbs the latent heat released by the motive steam inside the tubes.

The remaining feed, now slightly concentrated, is pumped to the next group of effects, which operate at a higher temperature. There the spray procedure is repeated, the remaining feed being pumped onward again until it leaves the hottest group of effects as concentrated brine.

Motive Steam Energy Supply

Almost any source of steam can be used to power the AQUAPORT MED. Motive steam of 1 atg or less is throttled down to 0.35 atg; above 3 atg, steam is reduced to a steam jet ejector which recompresses and recycles vapor from the cooler end of the plant in order to achieve a substantially higher Economy Ratio.

The steam is supplied to the tubes of the hottest effect. There it condenses, giving up its latent heat to the salt water flowing over the outer surface of the tubes. While condensation is taking place on the inside of the tubes, a nearly equal amount of evaporation is occuring on the outside. After passing through a brine droplet separator to maintain purity of the distillate, the vapor is drawn into the tubes of the next effect, which is operating at a slightly lower temperature and pressure.

The evaporation-condensation process is repeated along the entire series of effects, each of which contributes a significant amount of additional distillate. From the last effect, all the remaining vapor is liquefied in the Heat Rejection Condenser by sea water coolant.

The Distillate

Fresh water from the first effect is collected in a condensate tank. Part of this distillate is returned to the steam generator, the excess, above the original quantity of motive steam, flows into the first of a series of special chambers which collect the distillate from each effect. Since the vapor space of each collector is ducted to the cooler condensing section of the next effect, part of the distillate flashes off, cooling the remaining product stream while recovering heat and returning it to the main body of Heat Recovery Effects. The flowing product stream is thus cascaded and flash cooled at stages, the last effect is drawn off, necessarily the total efficiency of the process. The cooled distillate is finally discharged to storage by the product delivery pump.

The product is totally pure water. It is fresh, potable and soft, averaging only 20 ppm of dissolved solids.

Brine and NCG Disposal

The concentrated brine from the hottest effect is, like the distillate, cascaded and flash cooled to recover its heat. After cooling, it is returned to the sea via the brine pump.

Non-Condensible Gases (NCG) are bled from each tube and flow collectively from one effect to the next. They are eventually concentrated at the coolest end of the Heat Rejection Condenser, and are finally evacuated by a steam jet ejector or mechanical vacuum pump.

The Plant

Rugged construction

Simple mechanical design

Few moving parts

Factory assembled effects

Easy site erection

No insulation required

Non-corrodable polypropylene & PVC piping

Control Controls, Instrumentation and Electrical Panel. Containing complete electrical system, push-button motor starters and controls. A central display of all instrumentation and controls allows easy supervision of plant operation. Instrumentation and controls connected to an integrated sequence sensitive safety alarm and shutdown system.
All instrumentation are of high quality and reliability to ensure steady operation with a minimum of supervision.

Saving through efficient combinations:

Aquaport MED and Electrical Power Plants

The AQUAPORT MED is the seawater distillation plant of choice for combination with:

- Steam turbine power plants
- Diesel engine power plants
- Gas turbine power plants

These low or zero energy cost waste heat sources can be employed to significantly reduce the cost of desalinated seawater.

Steam Turbine

Steam-powered electricity generating stations and AQUAPORT MED are ideally suited for each other. Turbine exhaust steam pressures as low as 0.2 ata (60°C, 140°F) can be used with the AQUAPORT MED in contrast to other types of distillation plants requiring higher temperature (120°C, 248°F) and pressure steam supply. This results in low or energy costs allocated to water production with AQUAPORT MED since the steam has been more fully expended in the turbine, giving greater power generation for a given fuel energy input.

AQUAPORT MED has the built in advantage of broad-range load following capability, automatically adapting output to steam supply over a span of 40-120% of nominal capacity. In contrast to other types of distillation plants, no dump condensers are required and no steam is wasted during peak-load hours. Additionally, no high-cost auxiliary steam is needed during off-peak periods.

Diesel Generators and Gas Turbines

Waste heat from diesel generators and gas turbines may be utilized to produce steam for the AQUAPORT MED. A simple heat exchanger or waste heat boiler can enable the production of desalinated water at near zero energy cost. The waste heat from a diesel generator of 15 MW output can supply enough steam to produce 4000 tons of water daily. Similarly, a 15 MW gas turbine generator rejects sufficient heat for an average daily water supply of 7000 tons.

"Total Energy" Desalination Facility

Up to 80% of the fuel energy input to a diesel-powered generating plant can be utilized in the production of pure water. This is accomplished by combining two AQUAPORT models. The steam-driven AQUAPORT MED and the electrically-powered AQUAPORT VC (Vapor Compression). The diesel generator supplies electricity directly to the AQUAPORT VC unit, while the AQUAPORT MED plant uses diesel waste heat from lubricating oil, cooling water and exhaust gases streams.

Water production rates with waste heat and solar energy sources

Steam turbine power desalination plant

Waste heat desalination plant

Total energy desalination facility

SPECIAL ENERGY CONSERVATION PLANTS

Industrial Waste Heat

Petrochemical plants, glass and ceramics factories, municipal incinerators, beverage distilleries, plastics factories and a host of other industries can provide desalinated water as a primary by-product with AQUAPORT MED. Heat exchangers, waste heat boilers or stack gas heat absorption bundles can transform waste heat into usable steam for AQUAPORT MED installations.

Solar Energy

Solar ponds and flat-plate or tubular solar collectors can efficiently provide hot water of up to 80°C. AQUAPORT MED's unique low temperature heat requirements make both these sources practical for distillation of seawater.

Geothermal Heat

Hot water from geysers and springs, steam from fumaroles, hot rock deposits, stable volcanic activity, and other geothermal sources can be readily adapted to the requirements of AQUAPORT MED units.

Bringing Down the Cost of Water

The end cost of a cubic meter of desalinated water is dependent upon a large number of factors. A few of these are beyond the control of the manufacturer or the user: land acquisition cost, local labor rates, local taxes. But the vast majority of expenditures contributing to the final cost of pure water are definitely lower with AQUAPORT MED.

Initial Investment — An AQUAPORT MED plant, with low-cost aluminum alloy tubing, modular construction and simple control system, costs less to buy, less to install than competitive plants of comparable output.

Lowest Energy Cost — The use of low-grade steam means lowest possible energy cost. The possibility of alternative energy sources — solar, geothermal or waste heat — can reduce energy costs to that required for pumping only.

Energy contributes over 50% to the cost of desalinated water in both single purpose (water only) and dual purpose (water plus electricity) applications, the MED offers lower energy costs than are possible with high temperature MSF or other type distillation plants.

Single Purpose Plants. Economy Ratios (weight ratio of product water to heating steam consumed) of up to 14:1 are possible with MED plants operating at a maximum brine temperature of only 75°C (167°F).

These Economy Ratios are much higher than available in MSF plants of comparable cost and size and are achieved by use of a steam jet ejector vapor recompression cycle (see graph). With vapor recompression, advantage is taken of the surplus energy potential available in the steam of a conventional low pressure (Bata) boiler to substantially increase the Economy Ratio while still introducing motive steam to the first effect at a pressure of only 0.35 ata (73°C, 163°F).

Dual Purpose Plants. In dual purpose applications, energy costs chargeable to IDE's plants are less than half the costs charged to high temperature distillation plants. Even with a steam supply at only 73°C (163°F), the AQUAPORT MED can operate at Economy Ratios comparable to or even better than those of high temperature MSF plants of similar size which require 120°C (248°F) steam.

The economic value of 73°C (163°F) temperature turbine steam is almost 70% lower than that of 120°C (248°F) steam (see graph) since it has been more fully expended in the turbine and produces more electrical power for a given steam input to the turbine.

Independent studies of energy costs in dual purpose plants show that the AQUAPORT MED achieves costs lower than those of any other known distillation, reverse osmosis or freezing process for seawater desalination (see table).

Reduced Labor Costs — AQUAPORT MED's fully automated operation and low maintenance profile reduce staff requirements to a bare minimum.

High Plant Load Factor — Continuous operation at full plant capacity and high on-line availability are features of the AQUAPORT MED.

The AQUAPORT MED operates at unparalleled low temperatures reducing scaling and corrosion to a minimum. Scaling and corrosion are behind 90% of all problems plaguing conventional high temperature 90°C to 120°C (194°F to 248°F), distillation plants and causing reduction in plant capacity and availability.

Quick start-up and broad-range load following capability also maximize production, minimize water costs.

Low Maintenance Costs — With low temperature operation and minimal corrosion and scaling, maintenance costs with AQUAPORT MED are low because of reduced component failure, fewer parts replacements and smaller required spare parts inventory.

ENERGY COSTS FOR SEAWATER DESALTING PROCESSES *

Process	Maximum Brine Temp	Energy Source	Economy Ratio klbs Water/kBtu	Btu/lb Water	Cost of Heat $/MMBtu	Cost of Water $/kgal	Pumping Energy kwh/kgal	Pumping Cost $/kgal	Total Energy Cost $/kgal

World's Largest MED Desalination Plant

In 1979 IDE started construction of the world's largest MED desalination module at Ashdod, Israel. Utilizing back pressure turbine exhaust steam from an adjacent 50 MW electrical power plant, the giant AQUAPORT MED unit will produce 37,500 tons/day of pure distillate from the waters of the nearby Mediterranean Sea.

Design of the new plant was begun following evaluation of IDE's Eilat installation by the governments of Israel and the United States. The Eilat plant is a 12-effect system which provides 3,800 tons of water daily to the Red Sea resort town's 20,000 inhabitants, 18 major hotels, and a number of tourist facilities. The plant enjoys unprecedented efficiency, 99% on-line availability and an Economy Ratio approaching 12:1.

Highly impressed by the performance of the Eilat AQUAPORT MED plant and IDE installations in Iran, the United States government is taking an active role in the financing and development of the giant dual purpose plant. In return for technical knowledge it will gain, the USA is participating to the extent of $ 20 million of the projected $ 55 million total project cost.

Field erected because of its size, the Ashdod AQUAPORT MED module will be almost nine meters in diameter and 110 meters long. Its design calls for 14 Heat Recovery Effects and a Heat Rejection Condenser. Operating on low-grade 0.4 ata, 78°C (165°F), back pressure turbine exhaust steam and a maximum brine temperature of 74°C (165°F), its predicted Economy Ratio is 10.6:1.

Water costs in 1980 dollars, including amortization, for this type of plant in sizes of 37,500 to 375,000 tons/day should be about $ 0.40 per cubic meter, among the world's lowest prices for desalinated water of comparable purity.

Aquaport MED Models and Specifications

AQUAPORT MED units are manufactured in a wide variety of nominal capacity ratings, ranging from 1,500 to 37,500 tons/day. A plant may be comprised of up to 10 units for a total output of up to 375,000 tons/day of pure potable water. This quantity is sufficient for the needs of a highly industrialized city with a population of 1,000,000.

In addition to AQUAPORT MED, the table below shows a listing for AQUAPORT MEVC plants. These differ from the MED only in the addition of a vapor recyling system for use with input steam pressure of 3 ata and above to achieve higher economy ratios at a lower specific energy cost.

The table below details the technical specifications for several typical units. It must be borne in mind that IDE can manufacture all AQUAPORT models to customer requirements.

Model No.	MED 2000	MEVC 2000	MED 5000	MEVC 5000	MED 37,500
Nominal capacity (tons/day)	2000	2000	5000	5000	37,500
Number of heat recovery effects	12	10	12	12	14
Economy ratio (kg distillate/kg steam)	8.6	10	8.6	11.5	10.5
Seawater supply rate (tons/hr)	460	450	1500	1000	11,000
Seawater supply temperature (°C)	25	25	25	25	25
Motive steam pressure (ata)	0.35	8	0.35	8	0.4
Steam flow rate (tons/hr)	9.7	8.3	24.2	18.1	150
Process power consumption (kw)*	120	100	250	250	2050

DESALINATION PLANTS REFERENCE LIST

Over 120 AQUAPORT Vapour Compression and Multi-Effect Distillation units ranging in capacity from 30 to 4,000 m^3/day each, have been sold throughout the world including, Spain, the Canary and Balearic Islands, Italy, Venezuela, Peru, Iran, United States and Israel. Typical of these are the plants listed below.

OWNER	LOCATION	TYPE-SIZE OF UNITS
"Hocasa"-Hotel San Antonio	Lanzarote, Canary Islands, Spain	*VC-200 m^3/day
Cabildo de Lanzarote	Famara, Lanzarote, Canary Islands, Spain	VC-350 m^3/day
Caja Insular de Ahorros de Gran Canaria	La Santa, Lanzarote Canary Islands, Spain	VC-400 m^3/day
Jandia Playa Hotel	Fuerteventura, Canary Islands, Spain	VC-450 m^3/day
La Aldea de San Nicolas Tolentino	Gran Canaria Canary Islands, Spain	VC-250 m^3/day
Cabildo de Fuerteventura	Puerto de la Rosario Canary Islands, Spain	VC-500 m^3/day
Municipality of Galdar	Galdar, Canary Islands, Spain	VC-500/200 m^3/day
Hierro-Peru	San Nicolas, Peru	VC-500 m^3/day
Instituto Nacional de Obras Sanitarias	Los Roques Venzuela	VC-75 m^3/day
Imperial Iranian Air Force	Kish, Iran	VC-200 m^3/day
Imperial Iranian Air Force	Bushire, Iran	VC-250 m^3/day
Imperial Iranian Air Force	Bushire, Iran	VC-300 m^3/day
Imperial Government of Iran	Bandar Langeh, Iran	VC-500 m^3/day
Kish Island Development Organization	Kish Island, Iran	**MED-2,000 m^3/day
Imperial Iranian Navy	Bandar Abbas, Iran	MED-2,000 m^3/day

Consider RCC for its systems engineering approach

Resolving challenging waste and process stream management problems for clients is an important service at RCC. (1) We analyze your needs and design a system to meet them. (2) supply and install the equipment. (3) train the operators, and (4) start the system. Clients still rely on us for such services as parts-replacement expediting. Our customers call this total system responsibility the best in the business.

We're fully prepared to help you determine your requirements in the specific application of the Brine Concentrator or any other waste treatment system.

Resources Conservation Co

Brine Concentrator systems

Wastewater volume reduction

Energy-efficient resource recovery

Unique process requirements call for innovative solutions

Industrial water management frequently requires treatment of aqueous streams fabricated with inorganic salts and organic matter. As these materials precipitate, conventional water treatment equipment is rapidly scaled and fouled.

In contrast, Resources Conservation Co. (RCC) Brine Concentrators operate at supersaturated concentrations without scaling, eliminating system fouling and allowing pure product water to be recovered continuously. Corrosion is minimized through the use of titanium and other advanced-technology materials.

Scale-free operation increases reliability

Brine Concentrators are vertical, tube-in-shell evaporators. Through a process of preferential precipitation, the system forces precipitating calcium sulfate and silica to build on existing seed crystals in the process stream instead of crystallizing as scale on heat-transfer surfaces.

The systems designed and installed by RCC are unsurpassed in high-performance energy-efficient operation. They concentrate industrial wastes or process streams into liquids and recover up to 98% of the water.

The system's high concentration capability greatly reduces or eliminates the need for evaporation ponds and is a substantial contributor to industry's efforts in meeting zero-discharge requirements. RCC has power experience in concentrating cooling tower blowdown and other industrial wastes. In the process, the maximum amount of pure water is recovered for reuse.

Our technology has been employed to treat waste streams from power generating plants, effluents from pulp and paper mills, discharges from petroleum and chemical streams, effluents from sulfuric processes and brackish waters.

RCC offers Brine Concentrators in many sizes, with unit capacities up to 840,000 gallons (4,000 gal/min) and in system combinations to satisfy greater processing needs. Models are adaptable to both new and existing installations.

The RCC Brine Concentrator is usually specified as a vapor-compression evaporator, but it is also available in a multieffect configuration. Although the vapor-compression model requires less operating energy, the multieffect design may be a cost-effective alternative in plants where excess steam can be used as the energy source.

RCC Brine Concentrators offer many cost-effective advantages

Because an RCC system prevents scaling and resists corrosives, its online availability consistently exceeds specifications. The Brine Concentrator can handle a wide variety of feed streams in an energy-efficient manner. It returns an extremely high ratio of pure, reusable water and minimizes disposal costs of concentrated saturated wastes.

Long, trouble-free service. Much of the credit for the Brine Concentrator's noncscaling operating dependability is due to an advanced-technology design. Special steel alloys, titanium, and the most dependable components are used to ensure a long effective service life. Materials for all components are especially resistant to corrosion and are specified to accommodate the chemistry of each particular application.

The system's control console has a mimic display for realtime monitoring. It is designed for unattended, fail-safe operation. These features and the system's easy accessibility for maintenance result in reduced operating costs.

High, pure-water recovery rates. Even after the circulating slurry has reached supersaturation, the Brine Concentrator will continue to recover pure water at rates averaging 98%.

Product water TDS averages 2 ppm and is suitable for use as boiler makeup. The low TDS distillate reduces the demineralizer load, thereby decreasing chemical treatment costs.

The system's high product water recovery rate could save on source water needs. Such reduction offers significant economies in sizing and space requirements for source water pipes and pumps in new installations.

98% pure water recovery stream in operation

Each of these Brine Concentrators is selected to process 275,000 gal/d cooling tower blowdown (at 3x), recover at least 98% of the input as pure water, and use only 90 kWh of energy for each 1,000 gal of high precipitation. In actual performance, each unit has rejected feed rates as high as 269,000 gal/day, recovered 98% of the input as pure water, and maintained operation at less than 90 kWh for each 1,000 gal of feed. Left to right: RCC Brine Concentrators installed at the Star Iron Tech, Inc., and Huntington Electric Power generating stations.

Process flow through a vapor-compression system

The schematic shows the process flow for the Brine Concentrator in its principal design—the vapor-compression configuration.

Incoming suspended solids large than 50 microns are removed by equipment in the Brine Concentrator system. The waste stream goes into a feed tank, where it is heated to hold acidity (pH) between 5.5 and 6.5 for decarbonating. The acidified waste stream is then pumped through a heat exchanger (higher rates is denser it into the mixing point. After passing through a separator (2) to remove carbon dioxide, nitrogen, and oxygen, the waste stream combines with a high concentrate in the circulating slurry (3). The forty-fold concentrate, recycled from the sump (4) is pumped through a heat exchanger (5) and then into the circulating system. The system maintains the supersaturation of the fluid by controlling the rate of the feed stream. The circulating slurry is pumped through a vapor-compression system (6) where the slurry is concentrated to the point of saturation. The saturated slurry is then pumped to the separator (7) where the concentrate is separated from the vapor. The concentrate is then recycled through the circulating system. The vapor is compressed (8) and returned to the circulating system (9) to provide the heat for the evaporation process. The condensate is then pumped through a heat exchanger (10) to provide heat for the feed stream. The condensate is then pumped through a heat exchanger (11) to provide heat for the circulating system. The condensate is then pumped through a heat exchanger (98) to provide heat for the feed stream. The condensate is then pumped through a heat exchanger (99) to provide heat for the circulating system. The condensate is then pumped through a heat exchanger (100) to provide heat for the feed stream.

1001

Treating combined wastes can greatly reduce disposal costs

The Brine Concentrator easily handles the highly concentrated wastes from cooling towers, demineralizers, boilers, ash sluice systems, flue-gas scrubbers, and chemical processes. In many combined applications, highly concentrated streams are reduced to a slurry about 2% of their original volume. This waste can easily be crystallized in a small solar pond or dryer. At one power generating station, a Brine Concentrator permitted a planned holding pond to be reduced from 530 acres to only 11 acres. Brine Concentrators are lower in capital and life-cycle costs than solar ponds, which are often considered as the only treatment alternative.

Substantial energy savings

In the vapor-compression configuration, the Brine Concentrator needs only 29 to 37 Btu/lb to concentrate typical cooling tower blowdowns and other waste and process streams. This converts to an electrical energy requirement of from 70 to 90 kWh per 1,000 gal of feed. Conventional evaporators consume from 200 to 400 Btu/lb of feed processed.

Usually, RICC vapor-compression Brine Concentrators are driven by steam compressors powered by electricity, but other power sources may be used to satisfy unique requirements. When customer plant steam is abundant, a multieffect Brine Concentrator offers special advantages.

A variety of wastes can be cleaned

The system's chemistry and operation can be adjusted to accommodate substantial variations in the quantity and chemical compositions of the TDS in waste and process streams. The stream chemistry examples illustrate the wide variety of wastes and other waters the system can efficiently process. Although total solids in the Brine Concentrator range from 115,000 ppm to over 350,000 ppm, the distillate contains less than 10-ppm TDS.

Brine Concentrator adapts to handle a variety of wastes

Top left: This is a typical cooling tower blowdown waste stream concentrated by a Brine Concentrator that recovers more than 98% of the water for reuse.
Bottom left: In this example, ash sluicing waste has been processed by a Brine Concentrator with 98% of the waste stream recycled.
Top right: This is an example where reverse osmosis waste has been reduced by 75%.
Bottom right: In this case, 95% of a waste stream from an oil or shale retorting plant is recovered for reuse.

ZERO DISCHARGE AT NORTHWEST ALLOYS, INC. - A CASE HISTORY

Northwest Alloys, Inc., a wholly-owned subsidiary of the Aluminum Company of America, is located in Addy, Washington approximately 60 miles north of Spokane. The plant produces two important alloying metals, magnesium and silicon. Construction of the plant began in October, 1973 with the first magnesium being produced in March, 1976 and the first silicon metal in July, 1977. The rated yearly capacity of the plant is 24,000 tons of magnesium and 16,500 tons of silicon. The plant employs over 400 people and is located on a plant site of 240 acres.

Addy, Washington was chosen as the plant site because of its massive beds of dolomite, the raw material used in the magnesium production process, and of quartzite, which is required to produce ferrosilicon and silicon.

MAGNETHERM PROCESS

Northwest Alloys, Inc. uses about 400,000 tons of dolomite and 100,000 tons of quartzite annually. Conservative estimates indicate that there is at least a 15 year supply of these minerals at this location.

The magnetherm process is used to produce magnesium and Northwest Alloys is the only plant in the United States to use this European technology. In the process, dolomite is crushed, screened and

Freshwater from the Sea

Vapour Compression Evaporation

1. INTRODUCTION

Fresh water is not available everywhere and not always in sufficient quantities. However, it can be obtained from sea, brackish or river water.

The plants needed for this purpose are designed by us in accordance with our own know-how, delivered, erected (also on turnkey basis) and commissioned.

Our know-how relies on the construction of more than a hundred evaporation plants working by the "VERTICAL TUBE EVAPORATION (VTE) SYSTEM", which offers many advantages in the desalting of sea, brackish or river water.

Types of LURGI seawater desalination plants

The multiple-effect VTE process is chiefly used for large plant capacities. For medium-size capacities, LURGI has developed another new conceptual design for seawater desalting plants. These seawater desalination plants with vapour compression (VC), benefit from the experience gained from evaporation plants working with thermal vapour compression (steam jet vapour compressor - VC-J) or with mechanical vapour compression (turbocompressor - VC-E or VC-D).

They can be built with a capacity of up to 4,000 tpd in one unit.

2. FEATURES OF THE VAPOUR COMPRESSION PROCESS

The vapour compression process for seawater desalting meets to a very high degree the present-day demands for low energy consumption at low investment costs, as well as for high availability, thanks to a clear set-up and ease of operation. The plants can be employed wherever electrical energy or fuel oil (EL) is available.

Mechanical vapour compression plants are distinguished by the following features:

- a very small process water intake quantity (2 to 3 t/t of fresh water) since no cooling water is needed.

- low process water treatment costs owing to the small water quantities involved.

- a very low energy consumption

  VC-E: 14 to 18 kwh/t of fresh water
  VC-D: 3 to 4 kg of fuel oil (EL)/t of fresh water

- a high purity of the distillate obtained (less than 8 ppm TDS).

- a high availability, due to carefully selected corrosion-proof materials and minimal scaling, owing to the low operating temperature.

- low operation and maintenance labour costs, thanks to automatic operation and the use of plant components having been tested over the years. Special care is exercised in selecting the compressor.

- pretreatment of the seawater with both additives and sulphuric acid

- turbocompressor drive by electric motor or Diesel engine at option

- a large range of variation of the distillate quantity

- low requirements for erection labour and short erection time due to extensive premounting of the plants

- small volume of civil work

- autonomous operation of the plant possible by its own power generation set

Thermal vapour compression plants are characterised by:

- complete pre-assembly, supply as a package unit

- very low investment costs

- unproblematical operation due to simplicity of plant set-up

- autonomous operation of the plant possible by its own power generation system

3. PRINCIPLE OF THE PROCESS

3.1 MECHANICAL VAPOUR COMPRESSION
- TURBOCOMPRESSOR DRIVEN BY ELECTRIC MOTOR

After mechanical and chemical pretreatment, the seawater is heated to the evaporation temperature (60 to 80°C) in plate heat exchangers in countercurrent to the distillate and brine and enters the evaporator at the top. Evenly distributed over the tube plate of a vertically disposed tube bundle, it flows down as a film inside the tubes. The tubes are heated with steam on the outside, so that water is evaporated from the seawater film.

The vapour given off from the seawater is compressed polytropically in a turbocompressor and re-introduced into the evaporator as heating steam.

The steam condenses on the outside of the tube walls and, after heat exchange with the process water, it is obtained as salt-free condensate suitable for processing into drinking water or for direct use.

Plants with a capacity of up to 1200 tpd are furnished with one evaporator. For larger plant capacities, two or three evaporators are connected in series.

3.2 MECHANICAL VAPOUR COMPRESSION
- TURBOCOMPRESSOR DRIVEN BY DIESEL ENGINE

Under this process variant, the heat of the waste gases from the Diesel engine and of the cooling water is employed in addition to the distillate and brine heat for heating the process water. This process has been conceived for autonomous operation and is remarkable for the low costs it requires under partial load.

3.3 THERMAL VAPOUR COMPRESSION WITH STEAM JET EJECTOR

After the seawater has undergone mechanical and chemical pretreatment, it is heated in stages to the evaporation temperature (60 to 80°C) in the condenser and preheaters and subsequently reaches the first evaporator at the top, where it is evenly distributed over the tube plate of a vertically disposed tube bundle and flows down as a film

inside the tubes. The tubes are heated with steam on the outside, so that water is evaporated from the seawater film.

The vapour given off from the seawater, serves as heating steam in the second evaporator effect.

Part of the vapour produced in the second evaporating effect is compressed to a higher pressure in a steam jet ejector, employing steam from a steam boiler and is used to heat the first evaporating effect.

The other part of the vapour is condensed in the condenser, thus heating the process water, and is collected as saltfree condensate, together with the steam having condensed on the outer wall tubes of the evaporator. Part of this condensate returns to the steam boiler, whereas the remaining part is available for processing into drinking water or for direct use.

4. PRETREATMENT OF THE SEAWATER

At certain temperatures, untreated seawater will chiefly precipitate

calcium carbonate
calcium sulphate
magnesium hydroxide

on the heating surfaces.

Calcium carbonate is formed at low temperatures by thermal decomposition of hydrocarbonate. At higher temperatures (above 80°C), the hydrogen carbonate hydrolyses preferentially and results in the formation of magnesium hydroxide.

In fact, scale deposits on the heating surfaces reduce the output distillate and might increase the specific energy consumption.

The LURGI VC process eliminates magnesium hydroxide deposition by using evaporation temperatures below 80°C.

For the elimination of calcium carbonate scaling, two methods can be adopted:

1) Treatment of the seawater with additives (e.g. polyphosphate or polymeric carboxylic acids). These additives are to keep the calcium and magnesium carbonates in solution and thus prevent deposition on the heating surfaces.

   Experience has shown that scaling cannot be eliminated entirely. However, the deposits are loose and may be readily dissolved by a suitable acid (e.g. aminosulfonic acid); it is therefore advisable to flush the plant at certain intervals.

There is no fear of calcium sulphate deposits in VC plants either, because the temperature and concentration of the brine during distillation always remain below the calcium sulphate scaling curve, which runs between the saturation curves of the anhydride and hemihydrate.

Solubility of calcium sulphate

2) Treatment of the seawater with sulphuric acid. The sulphuric acid reacts with the hydrocarbonate forming calcium sulphate and carbon dioxide. The latter is drawn off completely from the seawater in a vacuum degasser.

The acidified and degassed seawater is adjusted to a pH value of 7.5 by means of sodium hydroxide before it enters the evaporator. This pH value ensures that, at the concentrations and temperatures prevailing in the VC plant, no magnesium hydroxide precipitates.

Solubility of $Mg(OH)_2$ in seawater

5. CONSTRUCTION MATERIALS

Reliability and availability are indispensable features of plants to producing drinking water and service water. We guarantee these features by careful selection of construction materials and testing. The metal laboratory of METALLGESELLSCHAFT, Frankfurt/Main, our parent company, assists us in these matters.

SELECTION OF CONSTRUCTION MATERIAL DEMONSTRATED FOR A VC-PLANT

6. CAPACITY RANGE AND SPACE REQUIREMENTS

We supply VC plants of 250 to 4,000 tpd in one stream. The capacity range of the plants with thermal or mechanical vapour compression is broken down as follows:

Thermal vapour compression:

250 and 500 t/day

Mechanical vapour compression:
(with Diesel engine or electric motor drive, at option)

500 to 1,300 t/day with one evaporator
1,300 to 2,700 t/day with 2 evaporators in series
2,700 to 4,000 t/day with 3 evaporators in series

The plants are equipped for outdoor installation and premounted to the largest possible extent.

Thermal vapour compression plants are sold as package units.

Technical Data

Mechanical Vapour Compression Plants

- salinity of brackish/seawater, in TDS	15,000 to 60,000 ppm
- salinity of the brine, in TDS	65,000 to 110,000 ppm
- salinity of distillate, in TDS	$\leq$ 8 ppm
- seawater temperature	up to 50°C
- seawater quantity:	
distillate output	3 : 1 to 2 : 1
- evaporation temperatures	60 to 80°C
- energy consumption /ton of distillate	
VC-E	14 - 18 kWh
VC-D	3 - 4 kg fuel oil

Thermal Vapour Compression Plants

- salinity of brackish/seawater, in TDS	15,000 to 60,000 ppm
- salinity of brine, in TDS	up to 80,000 ppm
- salinity of distillate, in TDS	$\leq$ 30 ppm
- seawater temperature	up to 45°C
- seawater quantity : distillate output	5 : 1
- evaporation temperatures	70 - 75°C
- energy consumption /t of distillate	
fuel oil	12 - 14 kg
electric energy	2.5 kWh

Space requirements of a 3-line VC-E plant installed outdoors, capacity: 3 x 1000 t/d

7. HOW MUCH DOES A TON OF DISTILLED WATER COST?

The water price is determined decisively by energy and capital costs. They depend on the effective temperature differential in the evaporator of the desalination plant.

The sum of energy and capital costs is reduces to a minimum value at a given temperature difference, depending on the local cost factors.

Water costs

The Price of one Ton of Water

Manpower	DM 0.20	(5.8 %)
Maintenance	DM 0.37	(10.8 %)
	DM 3.44	(100 %)

8. TREATMENT OF DRINKING WATER

Seawater distillate is not drinking water. It lacks the minerals required by the organism, human and animal. To obtain a chemically and bacteriologically flawless drinking water that does not damage the pipe network, the freshwater has to be processed.

For processing, the following treating methods have proved successful:

- aeration
- salinification to approx. 300 ppm by adding seawater
- acidification with carbon dioxide
- passing over dolomite or mixing with caustic lime, in order to obtain a calcium hardness of at least 1 mval/kg
- protective chlorination up to a chlorine residue of 0.2 to 0.3 ppm.

9. PRODUCTION OF BOILER FEED WATER

The distillate from a VC plant is processed into boiler feed water at very low costs, because of the residual salt content of the distillate, which is already low.

For large waterspace boilers and circulation boilers up to an operating pressure of 64 bar, softening by cation exchange resins in the sodium form is sufficient. The total hardness of the distillate is thus reduced to values smaller than 0.01 mval/kg.

For circulation boilers above an operating pressure of 64 bar, as well as for once-through boilers and injection water for steam desuperheaters demineralisation is effected directly in mixed bed exchangers. A mixed-bed exchanger consists of a filter bed with a mixture of strongly acid cation exchanger and strongly basic anion exchanger.

In those cases where a water-steam cycle exists, i.e. condensate is returned as boiler feed and the distillate from the VC plant is used solely as make-up water, condensate processing and distillate demineralization can be combined accordingly. To this end, mostly candle filters, precoated and unprecoated, are employed for condensate filtration, followed by mixed-bed exchangers for demineralizing the distillate and condensate.

10. WHEN IS THE VC PROCESS APPLIED?

For the desalination of brackish, river and seawater, various processes are available:

- distillation process
- freezing and hydration process
- electrodialysis
- reverse osmosis and
- ion exchangers

In addition to the reliability and applicability, the costs of the final product produced - service or drinking water in this instance - play a decisive part in the selection of a process. A comparison of the costs associated with the processes most frequently used - distillation, reverse osmosis and ion exchange - reveals an interesting function between the distillate price and the salinity of the water under treatment, at the present level of technology.

Water costs of different types of desalting plants

As a salinity of up to 500 ppm, water produced by ion exchange techniques is definitely the cheapest. For salinities ranging between 400 and 10,000 ppm, the use of plants working by the reverse osmosis principle should be given serious consideration. Above a salinity of 10,000 ppm, the distillation processes have been and still are unbeaten regarding their economics.

VC plants can be employed very economically where plant capacities of up to 4,000 tons per day and line are involved.

Thermal vapour compression plants with capacities of up to 500 tpd are remarkable for their

- low investment costs
- low construction and erection costs
- low operating and maintenance costs

while their consumptions are higher. They are particularly suited as water supply units for construction sites.

Mechanical vapour compression plants are designed for minimum energy consumptions and offer the same advantages as VC-J plants at somewhat higher investment cost.

They are very versatile in application, e.g.

- as plants for the production of boiler feed water in power plants
- as drinking and service water production plants for capacities of up to 4,000 tons per day and train
- as extension of existing desalting plants since in this case, the cooling water can be re-used as process water for the VC plant.

  Thus, no costs arise for a new seawater intake structure and for seawater treatment.

SEAWATER DESALINATION WITH VERY LOW ENERGY CONSUMPTION

L. CAVALIERI and G. NASSER

Bavaria Anlagenbau GmbH, Hasenheide 7, 8080 Fürstenfeldbruck (West Germany)

ABSTRACT

A desalination process is presented, employing a combination of VTE and MSF processes. A new development of compact titanium plate heat exchangers permit the vertical arrangement of 55 effects within a pressure housing 34 m height, with a 2,5 x 3,2 m base. This tower unit provides a fresh water output of 5000 m^3/day with a Performance Ratio of 40 (tons of fresh water per ton of supplied steam).

INTRODUCTION

A large scale prototype desalination plant has been developed based on a new patented plate heat exchanger design. This plant, operating as multiple effect process (vertical tube evaporation VTE + multi stage flash MSF) has been erected at Bavaria Anlagenbau GmbH, near Munich. A total process capacity of 5000 m^3/day can be reached by simply doubling the prototype's cross section width.

The plant's most important advantages are the extremely low energy consumption (Performance Ratio > 40 by thermodynamic evaluation) and improved operating characteristics.

Specifically this unique design offers:

1. A large number of effects because of compact heat exchanger design, their arrangement and economic production technique.
2. An effect interconnecting baffle system avoiding external pipework.
3. A Performance Ratio > 40, because 55 VTE effects and 75 MFS stages are combined, operating from 130 °C down to approx. 30 - 35 °C.
4. Maximum corrosion resistances as all heat exchangers are manufactured of titanium and all internal chamber surfaces in contact with seawater are made of monit.

5. Minimized scaling, as brine is passed only once through the plant housing and operation with reduced pH-values does not attack the titanium and monit structures.
6. Easily interchangeable VTE-evaporators that can be slid into and out of pressure housing.
7. Front and rear hydraulic operated covers giving immediate access to the heat exchangers. An inflatable sealing ensures pressure-tight housing covers.

PROCESS DESCRIPTION

(see Fig. 1)

There are 5 main components:

1. Preheater (1)

   Seawater pumped through the preheater to the top VTE effect (2) of the box is heated up to 130 °C. Heating energy is supplied partly by condensing vapors from the MSF stages (3) and partly from the VTE effects (4).

2. VTE-evaporator effects (5)

   They are forming the pressure chamber boundaries together with the vapor guiding baffles (6) and MSF flash stages (7).

   Over 55 effects the pressure drops from approx. 2,9 bar at the top to approx. 0.05 bar vacuum over the bottom effect.

   For the sections of normal and vacuum pressure the VTE plate side offers an extended cross section to accomodate the dropping vapor density. Because of a reduced VTE heat transfer surface, the average driving temperature is increased to have optimum adaption to the geometric and thermodynamic conditions.

   Brine is flashed at each VTE effect inlet point (8)

followed by the falling evaporation as the brine passes vertically downstream.

Starting from the top, seawater of 130 °C enters the first VTE-effect (2) and is evaporated by heating steam of 3 bar, 132 °C (A) which is supplied to the VTE effect plate side. The steam condenses and forms the initial fresh water passing down the 75 MSF effects (7).

Brine and fresh water vapors leave the VTE effect on the tube side.

The brine (15) collects on top of the following VTE-effect which is covered by water distribution elements (8). These elements serve to throttle and to accumulate the brine to a defined level. This insures equalized brine falling film characteristics in the tube profiles of the VTE evaporator below.

The fresh water vapors, (10) having left the VTE evaporator tubes are forced to stream horizontally via the baffle plates (6) and the centrifugal separators (11) to enter the next VTE-effect at the plate side and the preheater's tube side for condensation. The condensation causes a suction effect continuously drawing vapor to the condensation surfaces.

By entering and passing the VTE via both plate-side ends, the vapors experience a minimum pressure loss. Inside the VTE-plate -side structure the condensate runs off vertically (14) due to gravity and accumulates for horizontal discharge (13) in the lowest plate cross section.

In the VTE effect the vapor's heat of condensation is used as heat of evaporation on the tubeside for vapor generation. The temperature difference corresponds to the pressure drop at the brine throttling plate (8).

3. Baffles (6) with centrifugal separators (11).

As described above vapors are guided to the next following VTE effect plate side. Brine droplets are separated from the vapors by the centrifugal effect resulting from the radial baffle-forced vapor flow.

4. MSF-flash effects (7)

Condensate effluents from the VTE effects and from the corresponding preheater sections are accumulated to be flashed into the next pressure chamber for increased heating steam availability in the preheater section below.

For the 12 lower VTE effects the corresponding MSF effects are divided up into several pressure steps (12) in order to provide elevated temperature differences between condensate and seawater in the preheater section below - for optimum use of the available heat transfer area.

5. Run-off system (not shown in Fig. 1)

Brine collected over the VTE effects (15) and in the centrifugal separators (11) is passed down to the next pressure effect by means of a run-off system, acting as soon as a maximum liquid level is reached.

6. Inert gas discharge (17)

Inert gases are exhausted selectively by means of VTE internal scondary condensation of remaining vapors, along the lowest plate cross section of the VTE evaporator (13) starting as the midpoint of the VTE plate length (16).

VTE-evaporator:

an all-welded plate heat exchanger of patented profile structure (Fig.2) with plates of 0.2 mm titan-palladium material.

In the vertical passage the facing plate profiles form double fluted tube channels of 330 mm length and 5 mm hydraulic diameter (Fig.3). The tube profiles are intersected every 36 mm by horizontal tube interconnecting channels which act to equalize pressure and concentration of fall-film evaporation.

In the horizontal passage all the facing plate profiles form plates with sinuous flow channel characteristics providing a short condensate film run-off length (Fig.4).

TABLE 2:

VTE-evaporator data

No. of tubes per VTE effect	18 520	
Heat transfer area per VTE effect (in medium press.section)	491	m^2
Heat transfer surface per m^3 evaporator vol.	200 - 290	m^2
Heat transfer surface per kg titanium	1.1	m^2
Average heat transfer coefficient	4180	W/m^2K
Average temperature gradient per effect	1.74	K
Average temperature difference	1.0	K

Preheater

The preheater is designed with parallel plate heat exchanger units using the same plate profile and tube channel length as the VTE effect but without the double flute tube structure used in the tube profile. 0.4 mm titan-palladium plate elements are used.

As vertical upstream seawater is pumped through the plate side (Fig.4) it generates a sinuous turbulent flow characteristic.

In the horizontal passage product vapors condense in the tube profiles and the condensate runoff follows the tube interconnecting channels as vertical downstreams (Fig.5).

The condensate is discharged into the adjoining MSF chamber along a preheater pressure effect subdivision boundary (9). This boundary is formed by modification in the plate profile structure, creating a tight

contact between facing plates due to the pressure of seawater passing through the plate side.

dvt VTE-MSF DISTILLATION PROCESS
a breakthrough in performance and design

- minimum energy consumption:
  performance ratio of 40 (to fresh water per to heating steam) realised by the compact high performance BAVEX exchanger design arranged in 55 vertical VTE effects.
- extended plant life time:
  high quality materials as 0.2 mm thin titan palladium plates for the BAVEX VTE, and 0.4 mm thin monit plates for the BAVEX MSF condensor ensures
- corrosion free operation
- operation free of scaling:
  acid dosing for scale control not hazardous for the BAVEX exchangers made of titan and monit. Once through brine circulation.
- compact design:
  units for capacities of 10000 m^3/day will only require a ground area of 20 sqm. The height of the desalination tower reaches 35 m. There is no external effect interconneting pipework.
- competitive investment costs:
  compact prefabricated design, high efficent use of raw materials for the automatisized BAVEX exchanger production.
- reduced maintenance time:
  VTE effects are installed as a slide in and pull out system. Acess is given by hydraulicly locked tower front-doors (see photographs below) with inflateable sealing.

Opening of hydraulic locked tower front-door

The patented BAVEX hybrid exchanger as core element for the new VTE-MSF design

BAVEX

vertical view through the tube side cross section. The plate side flow path is seen as sinuous flow channels.

Weight and Material Consumption of BAVEX compared with tube & shell exchangers.

Development and operating experience with BAVEX Hybrid heat exchangers have shown that almost all advantages of plate type and tube & shell type exchangers have been optimized in one innovative heat transfer system. Conventional tube & shell type exchangers with Cu-Ni-tubes in seawater services are being replaced by hybrid exchangers of MONIT stainless steel or titanium.

Advantages of BAVEX hybrid exchangers are especially:

- Lifetime of MONIT approx. 5 times longer than Cu-Ni materials in seawater services and chloride solutions
- Lifetime of titanium not limited by corrosion as seawater services have shown.
- Less plot area required and less weight
- High heat transfer rates and low pressure drop
- Economic prices due to automic fabrication although high quality material is used.

Pretreated Seawater is pumped through the preheater (2)* to the top of the tower (1)* while it is heated by condensing vapors from the MSF stages (11) and the VTE-effects (7).

By external steam (3) the seawater is reaching its final temperature of 130 °C and is evaporating in the top VTE-effect (1) to form brine and the initial fresh water vapors.

The brine passes through the tube side of all 55 VTE effects as once through vertical downstream. From effect to effect the pressure and temperature is dropping to reach vacuum pressure and about 30 °C at the bottom of the tower.

Fresh water vapors are evaporating from the brine falling film in each VTE effect (7). In the next following VTE effect below these vapors are condensed on the plate-side and provide the heating energy in this VTE effect to cause new vapors forming from the evaporating brine on the tube side. The new vapors have a reduced temperature and pressure level and repeat the same process again in the following VTE effects.

The condensates (15) produced by each VTE effect runs off into the MSF stages (10). There, from stage to stage the condensate is flashed (11) to provide heating steam for the preheater (2).

Along the low pressure VTE effects the MSF stages are divided up into several flashing steps (12) to provide vapors on elevated temperature levels for preheating.

Inert gases are exhausted selectively by secondary condensation of vapors along the lowest plate cross section of each VTE effect (15).

dvt MSF desalination tower – flash chambers instead of VTE's

The advantages of the vertical tower concept and of the BAVEX heat exchanger are also avalable for the MSF process. Through 70 flash chambers the brine experience as vertical downstream minimized non equilibrium flash losses, resulting in a performance Ratio of 15 - a competitive alternative to the RO-process. A separate broschure of the "dvt-MSF tower" is avalable.

dvt VTE-MSF waste water-treatment tower – "zero-waste discharge"

The VTE process design applied for waste water treatment, for example treatment of the brackish water discharge from RO plants, will concentrate the brine over 25 effects. The brine discharge as waste stream will drop to approx. 10% of the feed water stream. This application of the dvt VTE-MSF process solves brine discharge and pollution problems or increases the fresh water capacity for remote locations.

1054 VEX - MSF condensor and BAVEX brine heater for retubing and increasing performance of existing MSF units

The BAVEX exchanger blocks of non corrosive monit or titan material can economically replace old, non efficient or corroded conventional tube & shell condensors and brine heaters in existing MSF plants. Improvements in the Performance Ratio and capacity are to be experienced due to the higher surface density of the BAVEX-system. A separate broschure of the "BAVEX-Evaporators, Preheaters and Concentration Plants" is avaiable.

dvt VTE-MSF process - powered by solar collector field

Photo of a model, showing the required collector area for a 10000 m³/day desalination tower including night storage capacity.

The high performance ratio of the dvt VTE-MSF process – increased by a factor 4 to 5 compared to conventional MSF-makes the concept of a large scale solar powered desalination plant feasible. Investment cost for solar collector field compared to desalination plant costs will drop to a ratio of approx. 1:1.

Dear Mr. Von Michaelis:

At present our membrane distillation devices are being used in two pilot plants for production of drinking water from seawater. We have not yet provided water for boiler makeup or battery water.

Although we believe our process has value for chemical concentration, this has not yet been tried except in laboratory-scale systems. We are currently testing our modules to ensure their durability.

I have enclosed a technical paper for your information. Feel free to call me or to visit our Ft. Myers, Florida pilot plant if you have further questions.

Sincerely yours,

David W. Gore

The Module

Salty or brackish water, at ambient temperatures, enters the spiral channel. It is progressively heated as it flows toward the center. A slight amount of heat (4°C) is then added, the feedwater flows along a GORE-TEX Membrane, and water vapor passes through the membrane, condenses, transfers the heat of vaporization and condensation to incoming water, then is forced out as pure distillate. The spiral design of the module makes it compact, strong, and efficient. *Note:* Temperatures are variable depending on (1) size of still/length of flow channel; and (2) applied energy.

The Process

The Membrane

This new process for the production of pure water is made possible by the development of GORE-TEX® Expanded PTFE (above, magnified 1500 times). GORE-TEX Membranes are microporous (completely impermeable to all particulates above .2 microns in size, including bacteria); chemically inert (immune to virtually all chemical attack, including concentrated chlorine solutions); hydrophobic (impermeable to water) and yet permeable to water vapor. These membranes are non-contaminating and are not subject to aging or decay.

Introduction

Distillation usually involves three steps. First, the feedwater is boiled, often violently. Water vapor and feedwater mist flow in the absence of air across a space, through a demister which removes most of feedwater droplets, and on to a relatively cool condenser surface. In the final step, the water vapor is condensed into distillate, which is drawn off.

The fundamental simplicity of distillation is compromised by the need for complete removal of all noncondensible gases. By leaking into vessels and blanketing the condensor surface, even small amounts of air seriously cut distillate production. Vacuum pumps, strong pressure vessels, deairing devices, and specially-constructed feed recirculation pumps are all necessitated by the harmful effects of noncondensible gases.

A number of distillation processes have been proposed which eliminate the need for creating a vacuum. Hodges[1] built an air/vapor system which moved the air along with the water vapor. Basin-type solar stills use this same principal, but circulate the moisture-laden air through natural convection rather than by mechanical means. Another approach using narrow vapor gaps does not rely on moving humid air, but rather on diffusion of water molecules through still air. Devices operating in this way have been called "diffusion stills."[2] A basin-type solar still (see Figure 1) acts as a diffusion still if the feedwater surface is close enough to the glass to suppress convection.[3]

Figure 1: Basin-type Solar Diffusion Still

In diffusion stills, water does not boil but evaporates non-violently at the feedwater surface. In principal then, demisters are unnecessary in diffusion stills. Since virtually no feedwater mist is formed, one might expect the distillate to be unusually pure.

These alternative approaches to distillation have not been commercially successful. They either require considerable energy to pump air/vapor mixtures, lack the means to recover the latent heat energy, or produce little water, considering the inherent capital cost of the device.

Membrane Distillation

One finding of the study of diffusion stills was that the length of the "diffusion gap" between the evaporating and condensing surfaces was crucial. Production per unit area per unit time was found to be inversely proportional to the diffusion gap distance. Unfortunately, there was no way to bring the evaporating and condensing surfaces close together without causing contamination of the distillate by the feedwater.

Certain hydrophobic, microporous membranes show the surprising property of allowing easy passage of water vapor, but of completely blocking flow of liquid water. Surface tension of the water prevents its passage through the sub-micron pores of the hydrophobic material. As an example, a Gore-Tex® membrane

made of polytetrafluoroethylene (PTFE) can be 80% porous and yet resist entry of water at 40 psi pressure.

If one of these microporous PTFE membranes is placed between the evaporating feedwater and the condensing surface, the danger of distillate contamination is eliminated. In fact, one side of the PTFE membrane can make contact with the feedwater while the other side is in contact with the distillate. The diffusion gap distance then becomes the thickness of the microporous PTFE membrane. Since these membranes can be made as thin as 25 microns (.001"), the productivity of such a device can be many times that of other sorts of diffusion stills. The limitation on productivity becomes not the membrane thickness but the means of supplying heat to the feedwater/membrane interface and removing the heat of condensation from the membrane/distillate interface.

Figure 2 shows a device which supplies heat to the feedwater/membrane interface by means of heated feedwater which passes across one side of the membrane. Part of this feedwater evaporates, and water vapor from the feed diffuses through the microporous hydrophobic membrane and condenses on the other side when it comes into contact with the relatively cool distillate. The distillate in turn is cooled by an impermeable sheet of metal or plastic which forms one wall of a chamber through which cooling water is passed.

Figure 2: Use of Two Bodies of Water at Different Temperatures

Heat of condensation must be removed rapidly from the membrane/distillate interface. This requires a minimally thin distillate layer. Use of a strong, supportive condensor sheet and proper placement of the distillate outlet allow the warm feedwater flow to "milk" the distillate from the membrane distillation module and keep the distillate layer minimally thin at all times.

If we measure the average temperature in the warm feedwater channel and in the cooling water channel, and make the simplifying assumption that these correspond to the feedwater/membrane interfacial temperature and membrane/distillate interfacial temperature respectively, then we have a measure of productivity. For the ambient temperature range, a device such as that shown in Figure 2 will produce about 12.3 liters/m^2 day per torr of vapor pressure difference across the membrane (.3 gal/ft^2 day torr). If 4% NaCl feedwater is 30°C and the cooling water 20°C, this vapor pressure difference is 13.7 torr, and the membrane distillation module produces 168 liters/m^2 day (4.11 gal/ft^2 day). This invention clearly holds promise for making use of ambient-level temperature differentials for the production of desalted water.

Recovery of Latent Heat

For many applications "free" thermal energy is not available. To the extent that heat energy is expensive, it is necessary to recover the heat of condensation for re-use. Figure 3 shows schematically how this can be done in membrane distillation. Fresh feedwater enters the module cold but is progressively warmed by the condensor sheet, so that it emerges from the module quite hot. The heater boosts this feedwater temperature slightly, and the heated feedwater passes back through the module on the membrane side, gradually losing its heat through evaporation. The feed finally emerges somewhat concentrated and only slightly warmer than it was when it first entered the module. The distillate flows from the unit nearly completely cooled by the fresh feedwater.

Figure 3: Recovery of Latent Heat in Membrane Distillation

The performance ratio f of the device in this example is:

$$f = \frac{(.8)(95 - 25)}{(99 - 95)} = \frac{(.8)(70)}{(4)} = 14$$

The factor of .8 allows for the fact that from 5% to 20% of the heat transfer is due to thermal conduction rather than to evaporation and condensation of the water. The exact value of this factor (called "membrane efficiency") depends on the feedwater salinity, the temperature drop across the membrane, the average temperature of the system, and the speed of the feedwater flow. As the feed is pumped faster, the stagnant boundary layer of cool, evaporating feedwater at the membrane interface is reduced in thickness, increasing both the membrane efficiency and the productivity.

One difficulty with a linear membrane distillation device such as shown in Figure 3 is that the feedwater channels must typically be one hundred feet or more in length. The module is made much more compact by wrapping the channels into a spiral configuration so that the hot end is at the center and the cold end is at the outside (see Figure 4). This eliminates the need for insulation and bracing, since a spiral is both compact and resistant to moderate internal pressures.

Figure 4: A Spiral-Wound Membrane Distillation Module

A membrane distillation module does not exhibit a fixed performance ratio or a fixed productivity. Instead, there is a tradeoff relationship between the two (see Figure 5). The particular values depend on channel length and geometry, upper and lower feedwater temperatures used, feedwater salinity, and membrane type.

Points on the curve are selected by varying the feedwater flow rate, with higher flows increasing productivity but decreasing the performance ratio.

Figure 5: Performance Ratio and Productivity Tradeoffs

In general, higher performance ratios are achieved by lengthening the flow path of the feedwater. For a spiral-wound module, this results in a module of larger diameter. Increasing the axial length of a spiral-wound module does not change the tradeoff of unit productivity and performance ratio, but increases the distillate production, heat requirements, and feedwater requirements in proportion to the axial length increase.

Spiral-wound modules built to date have achieved performance ratios of 14.2 combined with productivities of 71.2 liters/m^2 day (1.74 gallons/ft^2 day). Considerable improvement on this can be expected as the technology matures.

Advantages of Membrane Distillation

Because the feedwater does not boil, and since the vapor passes through pores of .2 to .45 micron size, the distillate emerges sterile, free of particulates, and very low in dissolved solids. Distillate resistivities of 1 megohm-cm have been measured while using 4% NaCl solution as feedwater.

Substantial productivities can be achieved using ambient-level temperature differences. This allows use of oceanic thermal energy and inexpensive solar energy collection schemes such as shallow solar ponds.

The ability of membrane distillation systems to operate effectively at ambient pressures greatly simplifies their design and operation. This has particular value in small installations and in locations where engineering resources are scarce.

Recovery of latent heat within a single module allows construction of small highly efficient units and modular system organization for larger installations.

The module is flexible in operation, so that it can "load follow" to make best use of variable sources of waste heat. This flexibility also means that productivity can be adjusted to demand and performance ratio can be varied with the changing cost of energy.

Commercial Availability

Spiral-wound modules are now being tested in Ft. Myers, Florida, to ensure the reliability of the current design. Modules producing 250 GPD and 1,500 GPD will be available next year.

The Hardware*

To meet our data base and graphics requirements, we selected the first microcomputer to couple a new 16 bit microprocessor with two million bytes of floppy disc capacity . . . the NEC APC. Two versions are available:

	DS-HO2	DS-HO3
Monitor (12")	Monochrome	Color
User memory	256K	256K
Printer (100CDS)	dot matrix	dot matrix
Arithmetic PU	32 bit	32 bit

Either system can, of course, support any other software for which it was designed . . . obtainable from your NEC dealer.

*Specification Sheets available upon request

The Liveware
. . . over 100 years of experience

Bruce M. Watson
President and Chairman of the Board
Over twenty-five years of desalination experience . . . with a marine engineering background and extensive research, development and practical field experience in the area of seawater chemistry, scale and corrosion control.

Dr. Tom G. Temperley, O.B.E., C. Eng.
Vice President and Board Member
Over thirty years of desalination experience . . . A recognized authority in the fields of corrosion and water treatment with emphasis on the operation and maintenance of major power/desalination complexes in the Middle-East.

Alvin L. Maxfield
Vice President and Board Member
Over twenty-five years of experience with computer and communications systems . . . including the development and design of hardware/software systems ranging from early mainframes to modern microsystems.

Robert E. Baille, P.E.
Senior Technical Advisor and Board Member
Over twenty years of desalination experience . . . with a diversity of process and equipment designs, including plant start-ups, commercial operations and the development and application of advanced concepts.

The System Designed for You, the User

The System

. . . begins with a basic hardware/software package giving its user access to a whole encyclopedia of desalting industry data ranging from pump supplier lists to plant specifications for existing key installations. Depending upon the selection of additional software options, the system can provide 24-hour per day technical support of various functions, from initial planning and process selection to operational diagnosis and troubleshooting.

Designed for the User

Facility Planner ▫ Project Engineer ▫ Component Designer ▫ Process Engineer ▫ Plant Chemist ▫ Operating Superintendent ▫ Researcher ▫ Supplier.

A First in the Desalination Field

The DS Series was born of a timely combination of the "micro revolution" and the rapidly expanding needs for specialist support of desalting plant operations . . . in particular, process monitoring, operational diagnosis and operator training. Other programs have followed as a matter of course . . . to support optimum design selections, to develop economic forecasts and to provide a comprehensive industry data base.

Each program is the product of many years of experience in the areas of engineering, plant operations, chemical treatment and computer applications. "Drafted" or edited by recognized authorities before encoding, every program is formatted with maximum use of graphics to clarify and enhance inputs and outputs.

All commands are multiple choice, menu-driven and in a language familiar to any practitioner . . . in the desalination field.

The Software Library*

Catalog No.	Description
DS-S05	Desalination Industry Data Base Specifications, seawater and process chemistry, and performance of key desalting installations. Suppliers, A/E's, R&D Organizations and Owner/Operators.
DS-S06	Techno-Economic Design — Thermal/MSF **INPUT:** Water requirements, energy and chemical costs, feedwater and site factors. **OUTPUT:** Process and chemical treatment specifications and capital costs.
DS-S07	Techno-Economic Design — Membrane/RO **INPUT:** Water requirements, energy and chemical costs,feedwater and site factors. **OUTPUT:** Process specifications (membrane and pretreatment) and capital costs.
DS-S08	TRIPOD™ I Monitor & Control — Thermal/MSF **INPUT:** Seawater chemistry, heat exchanger configuration and process conditions. **INPUT:** Operator prompts for efficient and safe control of chemical dosing and makeup flow. Displays plant performance, critical data and economics of fouling.
DS-S09	TRIPOD™ II Monitor & Control — Membrane/RO **INPUT:** Feedwater chemistry, pretreatment system, membrane configuration. **OUTPUT:** Operator prompts for efficient control of process streams and chemical dosage. Displays plant performance critical data and economics of fouling.
DS-S20	Multi-level Training by Process Simulation — MSF **INPUT:** Seawater chemistry, process design, and range of operating parameters. **OUTPUT:** Graphic displays illustrate effects of deviations and process upsets introduced by user-instructor or trainee. Program rates student response and suggests better alternatives.

Mr. Hans von Michaelis
Randol International, Ltd.
21578 Mountsfield Drive
Golden, Colorado 80401

Dear Mr. von Michaelis:

As Bruce Watson indicated, you had discussed with him the possible use of our services in applying Desalination Technology to the metallurgical processes.

At Bruce Watson's suggestion, I have enclosed an outline of my professional background. I have eighteen years' experience in the membrane area, involving the development, design, and application of the membrane processes. The applications have included not only brackish water treatment, but industrial water reuse applications.

As Bruce Watson may have mentioned, we have formed a team to offer our services to those wishing to evaluate the evaporation and membrane processes. We would be very much interested in applying our Desalination expertise to the treatment of metallurgical streams and would look forward with interest to working with you in this area.

Thank you for your consideration. If there are any further questions, please do not hesitate to call.

Sincerely yours,

Robert M. Quinn

CURRICULUM VITAE

NAME:

Bruce Morgan WATSON

POSITION:

Principal Engineer

EDUCATION

Queen's University, Kingston, Ontario
B.Sc. (Mechanical Engineering), 1952

Royal Naval Engineering College, Plymouth, England
(Marine Engineering Specialist) 1954

SUMMARY OF QUALIFICATIONS

Twenty-three years' theoretical and practical experience in almost all aspects of seawater desalination technology, with particular emphasis on diagnosis and correction of operational problems related to scale, corrosion, heat consumption and water production.

Conceptual designs, feasibility studies and economic evaluations of single-purpose and multi-purpose facilities.

Special expertise in: (a) use of empirically-derived relationships between the scale and corrosion potentials of plant streams and their composition, and (b) application of currently available countermeasures via process adjustments and chemical treatment.

Instruction of operating and laboratory staffs of more than thirty desalting facilities, in well over a dozen countries, in control techniques to minimize fuel consumption, scale and corrosion.

Market and technology assessments.

Broad range of personal and professional contacts throughout the desalting industry, worldwide. Previous resident assignment in Middle East.

Preparation of microcomputer software packages for use by station operating engineers and chemists to calculate from plant data: scale potentials, heat and material balances, fouling, and all resulting economic parameters by which to adjust type of treatment, cleaning intervals, etc.

CONCEPTUAL DESIGNS, FEASIBILITY STUDIES AND COST ESTIMATES / SCALE AND CORROSION DIAGNOSIS & CONTROL
OPERATIONAL TROUBLESHOOTING AND COST REDUCTION / STAFF INSTRUCTION / MARKETING & TECHNOLOGY CONSULTATION

CHAPTER 19

FREEZING FOR DESALINATION AND COOLING

The basic principles of refrigeration equipment for desalination by freezing is provided by SCHUTTE (1983).

At first, Randol started off this investigation with the idea that since some deep underground mines require cooling as well as water treatment, that the two processes might be combined in an energy-efficient manner. Discussions with South African mining company experts pointed out that as yet no perfect means has been developed to pump ice slurries underground without problems of the crushed ice consolidating and clogging lines, etc.

Tom Wolfe of the Resources Conservation Co. pointed out that the other distillation processes require much less energy than does freezing. Heat used was recovered in the process to preheat incoming feed so the process of distillation is more efficient energywise than expected.

Theo Stielau, before retiring from Delkor Technik of Johannesburg, indicated that his company had found more efficient large-scale freezing equipment which could reduce the cost of making ice considerably. He did not elaborate, but Delkor can be contacted as follows:

DELKOR TECHNIK PTY LTD.
Post Office Box 39744
Bramley 2018
South Africa
(011) 643-6751
Errol Amm, Director

No commercial operations were encountered where water is desalinated by freezing.

DESALINATION: A SOUTH AFRICAN PERSPECTIVE

Water Research Commission

FREEZING

9.1 Introduction

Desalination by means of freezing is based on the natural phenomenon that ice crystals are made up of pure water. Any impurities such as dissolved solids are excluded from the crystals and therefore when melted, the ice crystals yield pure water. Freezing resembles distillation in that a change of phase is involved but it has a number of advantages over distillation : it requires the transfer of less energy; needs almost no pretreatment and has minimal corrosion problems. Despite these advantages and research and development work since the 1950's seawater desalination by freezing has not become a commercial success. However, there still is potential for the development and use of freezing as a desalination process.

Problems encountered in freezing include handling and separation of the ice-brine slurry and washing the ice crystals free of salts.

9.2 Elements of the freezing process

There are four basic elements in all freezing desalination processes viz freezing, washing, melting and heat removal.

Freezing or formation of ice crystals may be accomplished by either of two methods; direct or indirect freezing.

In the direct process freezing is effected by flash evaporation of water at reduced pressure. The vapour formed absorbs its heat of vapourization from the remaining liquid. This cools the water below its triple point and ice crystals begin to form and release their heat

Notes: 1. The combined freezer (crystallizer) and melter in one vessel is a unit called a hydroconverter.
2. The compressor utilizes thin flexible metal blades. It is built specifically for the high-volume, low-pressure conditions found in the VFVC process.

FIGURE 9 1Schematic diagram of a freezing desalination plant using the vacuum-freezing vapor-compression (VFVC) process. (USAID 1980)

of crystallization to reheat the water back to its triple point so that more water can vapourize. These processes of boiling and freezing take place simultaneously in the freezer with feedwater being added and ice slurry and vapour being withdrawn. The vacuum-freezing vapour compression direct process has been developed to the stage where a commercial unit was produced.

Figure 9.1 gives a schematic illustration of the process (USAID 1980).

In the indirect freezing process, freezing is accomplished by vapourization of an immixible refrigerant such as freon in direct contact with the feed water. The pressure in the freezer is maintained below the boiling pressure of the refrigerant (but not of the water) so that the refrigerant vapourizes. In vapourizing, the refrigerant removes its heat of vapourization from the water causing part of it to freeze. The advantage of using a secondary refrigerant is that it vapourizes at a much higher pressure than water and hence the freezer can operate near ambient pressures. The specific volume of the vapour produced is much less than that produced in the vacuum-freezing direct process. This allows the use of standard commercial compressors, reducing capital cost and operation and maintenance problems. A process configuration is given in figure 9.2 (USAID 1980)

9.3 Practical application

Application of freezing processes for water desalination is still limited to pilot scale. One 375 m^3/d vacuum-freezing vapour compression plant was built and sold but the plant did not operate continuously and was later removed because of financial problems experienced by the owner.

FIGURE 9.2 Block diagram of a secondary-refrigerant freezing process for desalting seawater. (USAID 1980)

CHAPTER 20

CRITICAL COMPARISON OF DESALINATION PROCESSES

From an applicability point of view, it is clear that in mine-mill environments, desalination processes should, if at all possible, be avoided altogether. These processes are not inexpensive and usually contribute little to the profitability of an operation. Nor are they all that easy to design, operate, and maintain.

Given that all else fails and desalination cannot be avoided, selection of the appropriate desalination process would vary considerably from case to case, depending on:

- Nature and Volume of the Effluent to be Treated
- Alternatives Available for Brine Discharge/Disposal
- Purity of Water Required
- Operator and Maintenance Skills Available
- Power Costs
- Climate

In general for very low TDS solutions requiring desalination, ion exchange processes may prove to be the more cost effective means of desalination. Here we are talking about solutions with 120 mg/l TDS and below, or where only certain specific ions need to be selectively removed.

Where solutions above about 150 mg/l TDS up to 10,000 mg/l need to be desalinated, which covers the range in which most acid mine drainage and mill tailings effluent fall, then R.O. or EDR membrane processes appear attractive. However, scaling and pretreatment requirements for these waters may favor the seeded slurry R.O. process of the Resources Conservation Company before all others because this avoids the need for pretreatment and employs a rugged, simple R.O. module (but many of them) rather than a smaller number of more sophisticated and correspondingly more sensitive membrane modules.

At concentrations in excess of 10,000 mg/l, often evaporative desalination processes are called for and, again, for minewater-type feed solutions, seeded slurry thin-film evaporators may be considered. There are several types of distillation systems that can be considered as discussed in the previous chapter. The relative ease of operation and startup of the alternatives is compared from one to the other and with R.O. in Technical Presentation 750-3550 by Aqua-Chem, Inc. below, who also compare a variety of other parameters, albeit for seawater desalination.

A useful comparison of desalination technologies was prepared by the Bechtel Group, Inc. of San Francisco for the Metropolitan Water District of Southern California by ROGERS, et al. (1983). This comparison is reasonably current and, although an apology is made for the poor quality of the copy, the information contained in it is reasonably useful in making a comparison.

Conclusions made in this investigation include:

1) The technologies of desalination are complex and difficult to evaluate for all possible applicabilities--each has its own niche, and the boundary of its niche would change as the nature of the parameters change.

2) Companies involved in one of the technologies, e.g., evaporation, may well be much less experienced in other desalination technologies, e.g., membrane desalination or ion exchange and vice versa. They make the best case for their own product, often without understanding the merits of the alternatives.

3) The assistance of a skilled and experienced consultant in making comparative analysis and selections of equipment and suppliers for desalination would be highly recommended.

4) Several pilot tests to demonstrate R.O., EDR, and evaporation for particular applications have failed--i.e., pilot testing is highly recommended ahead of designing or ordering a full-scale plant.

5) Mine-mill solutions are not the same as seawater as far as their desalination process parameters are concerned--nor are the brine disposal alternatives.

6) In mine-mill applications, consideration can be given to inserting desalination processes as a means of concentrating valuable ions as well as for water recovery.

7) Combinations of more than one desalination process may be the best solution to a problem. A systems approach is essential in selecting and sizing desalination processes--again, unless these can be avoided.

8) The RCC seeded slurry R.O. and evaporation process summarized below overcomes the serious limitations on desalination presented by most mine-mill effluents.

PROCESS SELECTION GUIDE TO SEAWATER DESALTING

TECHNICAL PRESENTATION
750-3550

WATER TECHNOLOGIES DIVISION
aqua-chem, Inc.

INTRODUCTION

As desalting technology advances, old processes change and new ones are developed. This paper presents a comparison of the current commercial seawater desalting processes including mechanical vapor compression (MVC), thermo-compression (TC), multiple effect (ME), once-through multistage flash (MSF-OT), brine recirculation multistage flash (MSF-BR), and reverse osmosis (RO).

These processes are compared on the basis of maintenance and operating complexity and capital and operating costs. The comparison is based primarily on the experience of the authors and the company that they represent.

The goal of the paper is to help users and planners answer the question, "What process is best for me?" Although some of the comments are applicable to all size plants, the paper is directed primarily to plants less than 2,000,000 GPD capacity. Plants using a combination of processes or hybrid systems are not considered.

PART I PERFORMANCE COMPARISON

A comparison of desalting processes on the basis of ease of operation, complexity and maintainability is necessarily a subjective analysis. However, we have tried to quantify our rationalization and to substantiate our conclusions as much as possible.

Ease of Operation and Startup

Table 1 ranks the desalting processes from the easiest to the most difficult from an operation and

startup standpoint. It is fairly easy to see from the table why the processes are ranked the way they are on the basis of the startup sequence. It is not as readily apparent that the same ranking is applicable during normal operation.

Actually, none of the processes should be difficult to operate once they are operating. There are only three to five critical operating parameters which must be controlled closely to avoid rapid deterioration of the plant's performance. Probably the most difficult task in the operation of any desalination plant is the determination of the cause of a problem when it occurs.

In an RO plant the quality of the seawater or improper pretreatment should be suspect when problems occur. In a thermal process improper chemical treatment or venting, for instance, can cause reduction in capacity or corrosion or both. In any case, it is important for operators to log plant performance and for the owners to have qualified supervisors who can interpret the data to determine the source of a problem.

We do not feel there is a significant difference in the degree of operational difficulty between the processes. The table does show a significant difference in the startup time of the different processes. Startup time will vary substantially depending on the ability of the operators and the size of the plant. The times shown are based on average size plants and experienced operators. The times also are for the startup of only one train. If a plant consists of multiple trains, the trains are usually started up in series. In most installations startup time does not represent a very significant factor because the plants are on line continuously. It would be a significant factor, however, if the plant were to be shut down and started frequently.

We have not addressed the question of the difficulty of commissioning a new plant. This again will vary considerably with the process, quality of water, and size of the plant. However, this should be the responsibility of the plant's supplier who should thoroughly check out the plant and train the operators before the plant is turned over to the owner.

Complexity

Table 2 ranks the processes from the least to the most complex based on a comparison of the number of controls, alarms, chemical systems, other systems, and pumps as well as our experience with these processes. The simplified process diagrams, Figures 1 thru 6, will help the reader relate to Table 2.

Ranking Least to Most	1 RO	2 MSF-OT	3 TC	4 MSF-RH	5 MVC	6 MEE

Table 2. Complexity Comparison

Figure 1. Reverse Osmosis (RO)

Figure 2. Multistage Flash Once Through (MSF-OT)

Figure 3. Thermocompression (TC)

Figure 4. Mechanical Vapor Compression (MVC)

Figure 5. Multistage Flash Brine Recirculation (MSF-RH)

Figure 6. Multiple Effect

In our evaluation we have not taken into account the seawater intake or brine disposal. A supply of seawater is required for all of the processes although the quantity will vary considerably. The mechanical vapor compression process requires approximately two times as much seawater as distillate produced, whereas, reverse osmosis requires approximately three times as much and the other processes eight to ten times. The brine disposal system, including seawater return in some cases, is common to all of the processes. Here again, the MVC process has the smallest brine flow followed by RO, while the other processes have considerably larger flow rates. Since the complexity of these systems can vary wildly from site to site we have chosen not to consider them in our evaluation. Each user will have to make his own evaluation of the impact of the seawater intake and brine disposal.

Likewise, the quality of the seawater supply was not evaluated because it, too, will vary widely. The quality of the seawater has little impact on the complexity of thermal processes as long as the designer takes it into account and chooses proper operating temperatures and concentration levels. On the other hand, the quality of the seawater can greatly influence the complexity of reverse osmosis systems particularly in the area of pretreatment as shown in Table 2 under the heading, "Other Systems Which Could Be Required".

It is common practice for suppliers of reverse osmosis systems to recommend that the user obtain his seawater supply from beach wells. Experience shows that beach wells normally produce a good quality seawater at a relatively constant temperature and, therefore, minimize the amount of pretreatment required. Our evaluation reflects this practice and assumes the seawater supplied is of such a quality.

All of the thermal processes require a steam supply which is not required by reverse osmosis systems. The quantity of steam required by the MVC process, however, is very small compared to the other thermal processes.

It is believed that the ranking given the processes is reasonable, although the differences between some may not be very great. The degree of difference in complexity of the processes is left to the opinion of the reader.

Maintenance

It is not possible to quantify the subject of maintenance when comparing the various desalting processes. In Table 3 they are ranked, based on experience, from the process requiring the least to the most maintenance. The following discussion attempts to justify this ranking by discussing each process in turn.

Ranking	Process
1	TC
2	MSF-OT
3	MSF-BR
4	RO
5	ME
6	MVC

Table 3. Maintenance Comparison

The TC process is ranked as the easiest to maintain primarily because it is usually a very low temperature plant. Therefore, even though TC is a thin film process, there should be very little scaling. Occasional acid cleanings will be required because some scaling will occur, but such occurrences should be very infrequent, probably less than once a year. Also, because of the low temperature, corrosion problems should be minimal even with steel shell materials. The number of pumps and controls are few and, since the compressor has no moving parts, it requires very little maintenance. The process becomes slightly more complex and requires more maintenance if a reboiler is needed to prevent condensate contamination of the distillate or if a distillate sterilizer is required.

The MSF-OT process is ranked second, primarily because it is a non-acid process. Corrosion may be a problem particularly in the hot end where the gases will be released, but this problem can be minimized by using proper materials, lining, and venting. Here again, the number of pumps and controls are minimal. The plant will have to be acid cleaned periodically, probably two to four times per year, depending on the type of scale control chemical used, the top operating temperature, and the quality of the seawater.

The MSF-BR process is ranked third behind the MSF-OT process because it has more pumps and controls and because it is typically an acid plant. If the plant uses a non-acid chemical for scale control, maintenance should be very similar to the MSF-OT process. History has shown that maintenance of acid plants has been relatively high because of corrosion problems and the difficulty in keeping the pH control system operating properly. These problems can be lessened by using better materials, more extensive linings and better operator training.

The reverse osmosis process has been ranked fourth, although there is not much experience by which to judge this process. It is reasonable to assume corrosion problems and maintenance will be less than the early MSF-BR acid plants, due to the materials of construction used in this process and the low operating temperatures. Nevertheless,

there are a number of reasons which lead us to believe that maintenance will be greater than modern MSF processes. The process normally uses acid for scale control and, thus, will have the same problems keeping the pH system functioning properly. There are many permeators in an RO plant each with corresponding connections, compression fittings, instrument connections, etc. Flow, conductivity and pressure drop data must be checked regularly for each rack in each block. Eventually the modules will have to be replaced on a more or less routine basis. The high pressure pump will probably require more maintenance than the usual centrifugal pumps used in the other processes. The RO plants are typically furnished in multiples of smaller capacity trains, although this has its advantages, it also multiplies the equipment involved and increases the amount of maintenance required.

The ME process has been ranked fifth because of the reported and known problems which have occurred in these film-type evaporators(1). These plants are typically acid treated for scale control and, thus, are subject to potential corrosion problems. The ME process typically uses a thin film evaporator with evaporation occurring on the liquid surface. These plants are more prone to scaling problems due to concentration gradients, and maldistribution of brine over the heat transfer surface(2). Controls and instruments are similar to MSF plants, but there are additional pumps to transfer the water between effects.

The MVC process has been ranked last because of the previously mentioned difficulty of scale control with thin film, acid treated evaporators and because of the added maintenance associated with the compressor and support equipment. Many of the problems associated with MVC plants have been caused by corrosion and misoperation, but nevertheless are real.

It is our opinion that any of the processes can achieve an acceptable level of maintenance if the process, materials of construction, and operating conditions are selected to suit the application, the seawater, and the quality of operators and supervision. On the other hand, any process can be a maintenance headache if it is misapplied or if it is not properly operated and maintained.

PART II COST COMPARISON

Economy

The economy, defined as the pounds of distillate produced divided by the energy input expressed in thousands of Btu's, is an accepted and convenient means of comparing the energy efficiency of desalination plants. Table 4 shows, roughly, the practical economy (E) range of the seawater desalination processes discussed in this paper, with TC and MSF being at the low end of the E range and RO being at the high end.

The TC process is ideal for the end-user who has high pressure steam which he intends to use for evaporation. Rather than reduce the steam pressure through a control valve for use in a MSF or ME evaporator, it can be reduced through a thermocompressor which boosts the E at a relatively small capital cost. The TC process is normally used with a multiple effect evaporator having two or more effects and, therefore, is really a combination TC/ME process. By using a large number of effects, economies greater than 10 can be achieved.

The TC process is used to improve the E of desalination plants when operating at low temperatures, 165°F or lower. There is little or no advantage to using a TC process at higher temperatures. The available temperature difference is small because of the low operating temperature and, as a result, heat transfer surface requirements become very large at high economies. Therefore, the top practical economy is about 10 although this would be quite expensive compared to MSF (3).

The maximum practical economy for a MSF evaporator is about 12. Of course, higher economies are theoretically possible and some have been built, but there are several problems associated with them. As the E is increased, the number of stages must be increased. Thus, the stage temperature differential decreases and losses such as boiling point elevation (BPE), pressure drop through the condenser and entrainment separators and, especially, flash suppression become significant. This decreases the designer's margin of error. The practical maximum number of stages is between 40 and 50 making the cost of MSF plants prohibitive at economies greater than 12.

Process	TC	MSF-OT	MSF-BR	ME	MVC	RO
Economy (Lb/1000 Btu)	3-10	3-12	3-12	10-15	17-33	30-200
Type of Energy	Hi Press Steam	Lo Press Steam or Hot Water	Lo Press Steam or Hot Water	Lo Press Steam or Hot Water	Elect. or Hi Press. Steam	Elect.
Practical Top Operating Temp (°F)	120-165	170-240	190-250	185-240	170-215	32-100

Table 4. Economy, Energy and Temperature Comparison

Table 4 shows that the range for a ME is between 10 and 15. ME evaporators are in service with economies well below 10, but the practical low-end boundary is fixed at 10 because of the advantages of MSF with respect to ME in low E applications. As mentioned in Part I, the MSF process is ranked higher than ME on the basis of simplicity and ease of operation. ME does not offer any significant advantages with respect to MSF at lower economies, but, the ME process has overriding advantages at economies above 10. Since there is no flash deviation in the ME process, temperature differential losses are limited to BPE, which is easily predicted, and to small pressure drop losses through vapor ducting and entrainment separators. So, compared to MSF, the designer is left with a much greater margin of error as E is increased.

PR	MSF	ME
12	1.0	.85
10	1.0	.88
5	1.0	.92

Table 5. Relative Evaporator Costs

Another advantage of ME, with respect to MSF, is the capital cost savings which is directly proportional to the E. Table 5 shows the relative savings as a cost ratio of ME/MSF. The exact value of these ratios is less important than the fact that the savings does exist and that it will increase as E increases.

The ME, MSF, and TC processes use heat energy at an elevated temperature and then, after a series of effects or stages release the energy to a heat sink. Thus, the initial investment of latent heat of vaporization is finally lost from the evaporator plant to the heat sink. In contrast, a MVC evaporator continually recycles the latent heat of vaporization using a vapor compressor (heat pump). Mechanical energy is usually input at the rate of 30 to 50 Btu/lb of distillate compared with 70 to 360 Btu/lb of distillate for a comparable ME or MSF evaporator.

The E of a MVC plant is proportional to the pressure differential (or polytropic head, in compressor jargon) developed by the compressor. The following equation demonstrates how the E of a MVC depends on the compressor's polytropic efficiency (η poly), polytropic head (H poly) measured in feet of steam, and the motor efficiency (η M).

$$E = \frac{7.7 \times 10^6 \, (\eta \text{ poly}) \, (\eta \text{ M})}{\text{H poly}}$$

Example: H poly = 20,000 ft
η poly = .77
η M = .9

$$E = \frac{7.7 \times 10^6 \times .77 \times .9}{20{,}000} = 27$$

The polytropic head for a commercially available, single-stage, centrifugal compressor ranges from 6,000 to 40,000 feet. The range typically employed for evaporation is 16,000 to 26,000 feet. Thus, the practical E for MVC processes ranges from 17 to 33.

The E of the RO process without power recovery ranges from about 30 to 140. As the following equation demonstrates, it depends primarily upon the pressure required across the membranes (Δ P expressed in PSI), the recovery rate (R), the efficiency of the pumps (η P) and the motors (η M), and the specific gravity (SG) of the feed.

$$E = \frac{3.37 \times 10^6}{(SG)} \times \frac{\eta \text{ P} \times \eta \text{ M} \times \text{R}}{\Delta \text{ P}}$$

Example: R = .35
ηP = .80
ηM = .95
Δ P = 900 psi
S.G. = 1.03

$$E = \frac{3.37 \times 10^6 \times .80 \times .95 \times .35}{900}$$

E = 96.7 lb/1000 Btu

The preceeding equation is valid for a one pass system without power recovery (PR). The E will be decreased somewhat by the addition of a second pass. Power recovery, on the other hand, will substantially increase the E of an RO plant. Relatively high energy exists in the RO blowdown stream which constitutes 65 to 85% of the feed stream and is at a pressure which is only 5% or so below that of the feed pressure. Power recovery turbines are commercially available with 65 to 85% efficiency and serve to reduce the energy consumption of the plant by as much as 45%, boosting E by 80% (4).

Type of Energy Used and Its Value

ME and MSF use low pressure steam, at 50 psig or less, or hot water. TC uses high pressure steam at 70 psig or higher. Either electricity via an electric motor or high pressure steam via a turbine can be used to drive a mechanical vapor compressor, although an electric motor is normally used. RO uses electricity. Table 4 summarizes the type of energy required for each process.

The economy is a useful comparison for plants that use an identical energy source but, since it doesn't account for the value of the energy consumed, it is not always a useful measurement when comparing plants that use different energy sources. A MVC evaporator may have a capital cost equal to and an E three times that of a MSF plant, but MSF will be the more economical process if the value of the energy to run the MVC is more than three times that of the MSF. The point being that the economy is only truly meaningful when it is examined together with the cost of the energy source.

In most cases it is very difficult to evaluate the true cost of electrical or thermal energy and everyone goes about their evaluation differently. However, some fundamental truths hold. For instance, the transformation of energy makes the final, useful Btu or KW more expensive due to energy conversion inefficiencies. Thus, the closer a desalination plant can get to the root source of energy -- that is, the fewer the transformations -- the less expensive the energy.

For example, a single purpose thermal plant would require a boiler supplying steam exclusively for the desalination plant. With a boiler efficiency of 90%, a gallon of fuel having a heating value of 150,000 Btu would yield 135,000 Btu's of useful energy. But if the desalination plant uses electricity as its energy source the fuel would first have to be converted to electrical energy. If the electrical energy is generated with a diesel generator at 25% efficiency, a gallon of fuel would yield only 37,500 Btu's of useful energy. Therefore, the electrical energy would cost 3.5 times as much, on a Btu basis, as the steam for a single purpose plant. Table 6 helps to compare the different desalting processes on this basis.

This comparison is valid only for single purpose plants. When dual purpose plants are used, the value of energy consumed will be considerably lower than the energy cost of fuel oil on a Btu basis and, in many cases, the user has waste heat available to operate a desalting process. Each case should be considered on its own merits. The user should evaluate what the various sources of energy cost and compare the desalting processes on the basis of these costs.

Process	E Lb/1000 Btu	Btu/ 1000 Gal.	KW/1000 Gal.	Form of Energy	Gal Oil/ 1000 Gal.
RO With PR	150	55,533	16.3	Electrical	1.48
RO Without PR	90	92,555	27.1	Electrical	2.47
MSF-OT,MSF-BR,ME	10	833,000	243.9	Steam	6.17
MVC	27	308,520	90.3	Electrical	8.23
TC	5	1,666,000	487.8	Steam	12.34

Table 6. Energy Requirements for Single Purpose Plants

Capital Costs

The capital cost of a plant is influenced by numerous variables, but, of these, the two most important are capacity and economy.

Economy should be chosen to yield the lowest unit cost of water. The cost of water can be defined as dollars per thousand gallons and is proportional to capital cost (installed plant cost, financing package, depreciation, etc.) and inversely proportional to operating cost (energy, chemical and spare parts cost, staff salaries, etc.). The capital cost varies directly with economy; operating cost varies inversely with economy. Therefore, the optimum economy is the one for which the combination of capital and operating cost yields the lowest cost of water.

Capacity, more so than any other variable, is under the control of the end user. The easiest way for an end user to cut capital cost (and total cost of water) is by reducing the capacity. Thus, it is extremely important that accurate water needs be determined. On the other hand, it is also important for the user to realize that the cost of, say, doubling the capacity of a plant, during the planning stage, will not double the cost. In fact, the cost will only be increased by about 50%. Doubling plant capacity after the initial capacity has been installed, however, will about double the cost of the total plant. This phenomenon is known as economies of scale and leads to a very useful relationship known as the six-tenths power rule.

If the cost of Evaporator A is known and the cost of Evaporator B, which has twice the capacity, but is identical in every other respect, is unknown, the cost of Evaporator B can be estimated by using the six-tenths power rule:

$$\text{Cost Evap B} = \left(\frac{\text{Capacity Evap B}}{\text{Capacity Evap A}}\right)^{.6} \times \text{Cost Evap A}$$

$$\text{Cost Evap B} = 2^{.6} \times \text{Cost Evap A} = 1.5 \times \text{Cost Evap A}$$

An equation of the same general form can be used to estimate the impact of economy on an otherwise identical plant. That is, if the cost of Plant C with E of 6 is known and we want to determine the impact of changing the E to 10 (Evap C'), then the following equation applies:

$$\text{Cost Evap C'} = \left(\frac{\text{E Evap C'}}{\text{E Evap C}}\right)^{.7} \times \text{Cost Evap A}$$

$$\text{Cost Evap C'} = \left(\frac{10}{6}\right)^{.7} \times \text{Cost Evap C} = 1.43 \text{ Cost Evap C}$$

The cost of an RO plant also follows a similar pattern with changes in capacity. The economics of scale, however, are less noticeable due to the fact that they have already been realized by the membrane manufacturer and are reflected in the price of the membranes which account for about 50% of the plant's cost. The value of the exponent is about 0.9 and therein lies the reason why RO lends itself to modular design. That is, subplants, whose size ease shipping and installation and whose independent operation mitigate unscheduled shutdowns, can be built at about the same price as one large RO plant.

These power rules yield good approximations and are useful tools during the study phase of a project. (Note that the value of the exponents will change somewhat from manufacturer to manufacturer.)

Two other capital cost variables, top operating temperature and material selection, are also important. Top operating temperature is a major consideration in the case of evaporators and it affects different evaporation processes in different ways.

The advantage of a higher top operating temperature in MSF and ME plants is that it increases the total temperature differential across the plant. Since the heat transfer surface is inversely proportional to the temperature differential, the capital cost of the plant is reduced (capital cost follows the six-tenths power rule with respect to surface area) with higher temperatures. The disadvantage of a high operating temperature (especially if it makes acid treatment necessary) is the increase in equipment failure due to corrosion. Unfortunately, this disadvantage is not as easy to quantify because it has a long-term effect that is obscured by chemical treatment as well as maintenance and operator skill. As the temperature is increased, though, one can be certain that the corrosion potential is also increased and corrosion, over the long run, can cancel the initial cost savings.

The top operating temperature of the once-through MSF process is limited by the temperature sensitivity of the non-acid scale control chemicals. High temperature additives make operation up to 240°F possible. The practical range is from 190 to 240°F. The brine recirculation MSF process's top temperature is limited by sulfate scale precipitation and its minimum operating temperature is the point where the additional capital cost exceeds the chemical treatment savings with respect to MSF-OT. Its practical range is about 170 to 250°F. ME's top temperature is also limited by sulfate scale precipitation; its practical range is about 170 to 240°F.

The same advantages and disadvantages apply to MVC, but the capital cost savings are realized in a different way. If the operating temperature is lowered in a MVC evaporator, the specific volume of the stream increases, making a larger size compressor necessary to handle the increased volumetric flow rate. For example, a plant having a volumetric flow rate of 40,000 ACFM at 212°F would have a volumetric flow rate of 95,364 ACFM at 170°F. This would make a larger compressor necessary, one that would cost approximately 60% more. Since the compressor is a very substantial cost component of the total system, the user should study carefully the benefits versus the costs of lowering the maximum brine temperature in a MVC plant. The practical top operating temperature range is 170 to 215°F.

The cost of a TC plant is not greatly affected by changes in the top operating temperature. The compressor is relatively inexpensive and changing its size will not significantly impact the total plant cost. The plant cost may, in fact, be reduced by lowering the maximum brine temperature since the evaporator vessel can then be constructed of less expensive materials such as carbon steel, without danger of excessive corrosion. The practical top operating temperature range is 120 to 170°F.

RO operates at ambient temperature and the only limitations are those set forth by the membrane manufacturers to protect the membrane materials and ensure maximum membrane life. A summary of the practical top operating temperature range for the different processes appears in Table 4.

As mentioned, material selection has an important impact upon the cost of a desalination plant. The material selection decision, however, becomes easier in the case of small evaporators. Evaporators with less than 200,000 GPD capacity are often constructed of copper-nickel simply because the cost savings of carbon steel is not sufficient to warrant the added corrosion risk. Table 7 shows the savings realized by constructing typical MSF vessels of carbon steel instead of copper-nickel.

Capacity GPD	Relative Plant Cost (Carbon Steel Cu-Ni)
70,000	95
200,000	90
1,250,000	86

Table 7

The selection of the tubing material is another important cost decision in selecting an evaporator process. Titanium tubes, for example, are much more expensive than Cu-Ni 90-10 tubes, but they should give the user a much longer life, particularly if acid is being used for scale control. Economic compromises in the material selection process must be studied carefully in the light of the potential for long-term deleterious effects.

Materials used in a RO plant are more straightforward and usually consist of aluminum bronze or stainless steel for the high pressure pump, stainless steel for high pressure piping, and PVC or RFP for low pressure piping. Iron bearing metals should be avoided in the feedwater system because iron fouls the membranes.

Two other capital cost factors worth mentioning are standard design and overspecification. The sixth-tenths power rule is not applicable in the case of standard versus custom-designed plants. For example, the six-tenths rule suggests that two half-size plants together will be 30% more expensive than a full size plant. But the rule does not hold if the half-size plants are standard and the full-size plant is a custom-made product. In fact, the two standard-size plants may be cheaper!

Normally the designer has complete control of the geometry or configuration of a plant. Economy, capacity, process type, even space allowances can be specified by the end user, but it is the designer alone who creates the geometry and a creative designer can substantially reduce costs. When users specify such things as cross-tube or long-tube design or tube diameter, they limit the packaging flexibility of the designer. Cross tube plants have been successful, long-tube plants have been successful and tube diameters of 3/8 inches and up have been successful. The end user should be careful not to overspecify because, in the end, it is the user who is penalized by costlier plants.

Capital cost decisions for RO plants are quite different from evaporators. Capital cost is affected by capacity, product water purity, use of power recovery, recovery rate and, probably most of all, by feed pretreatment.

A second pass may be required if the feed salinity is relatively high (greater than 40,000 ppm) or if a product water purity in the 70 ppm range is desired or both. This will add on the order of 15% to the capital cost of the plant. Power recovery units add to the capital cost of the plant, but usually have a payback period of 2 to 3 years.

The recovery rate affects the size of the feed intake, the pretreatment system, the RO pump and, ultimately, the capital cost. The capital cost decreases as the recovery rate is increased. As the recovery rate is increased above 20%, acid treatment of the feed becomes necessary to prevent scale. There is some uncertainty about the long-term affects of acid upon the materials in an RO plant. Thus, as is the case with evaporators, decisions to effect short term savings in capital cost may, in the long-run, result in diseavings.

The feed pretreatment system depends on the feedwater quality, its consistency and the quality of the operators and supervisors. Its cost varies with its complexity. A sophisticated system, which includes media filters, centrifuge cleaners, chlorinator, etc., may, cost as much as the RO membranes themselves, especially in smaller capacity plants.

Table 8 compares the relative capital cost of desalination processes on a $/GPD basis. The break point between large and small plants is about 250,000 GPD. The comparison is valid for plants with the same capacity, in addition, the ME, MSF and TC pressures were assumed to have the same economy. The comparison is based on the cost of equipment only, F.O.B. factory.

Process	TC	MSF-OT	MSF-BR	ME	MVC	RO
Relative Cost on a $/GPD Basis						
Small Plants	2.6	2.1	2.3	2.0	2.6	1.8
Large Plants	1.3	1.0	0.9	0.9	1.4	1.4

Table 8. Capital Cost Comparison

The table can be used to determine the relative $/GPD cost of different processes. For example, a million GPD RO plant will cost about 40% more than a MSF-OT, but a 100,000 GPD RO plant will cost about 15% less than an MSF-OT plant.

It is believed that the comparison is reasonable although one should realize that the differences may vary in actual circumstances. For instance, market competition, installation cost, seawater intake and disposal systems, shipping costs, etc. will have a considerable impact on the final installed capital cost differences.

Auxiliary Consumables

The section entitled "Type of Energy and Its Value" discussed the energy consumed by each process for separation of salt from water. Table 9 presents the auxiliary consumables, that is, approximate consumption of chemicals and auxiliary electricity.

Chemical consumption is expressed in pounds consumed per 1000 gallons of product water. The dosage rates and thus the consumption is dependent primarily upon the top operating temperature and brine concentration. The terms Poly, HTA and Acid stand for polyphosphate, high temperature additive and sulfuric acid, respectively.

Electrical consumption is expressed in KW per 1000 gallons of product water. The consumption does not include compressor power in the case of MVC or high pressure pump power in the case of RO - these are considered primary energy consumptions. The electrical consumption does not account for unusual intake or return requirements. The electrical consumption includes the electricity which is consumed within the battery points of the plant for feed, distillate, condensate, blowdown, recycle, and transfer pumps.

The flash plant electrical consumption is valid for a long tube design, the consumption will be about 30% higher for a cross tube plant.

Table 9 also lists cleaning and conditioning chemicals required for the various processes. The consumption of these chemicals will vary significantly from site to site and, therefore, no attempt was made to quantify this consumption.

Process	Top Temp (°F)	Chemicals		Electricity KW/KGAL	Cleaning/ Conditioning Chemicals
		lb/KGAL	Type		
MSF-OT	185 230	.18 .14	Poly HTA	14 13	HC1 or Sulfamic HC1 or Sulfamic
MSF-BR	185 230 250	.085 .12 2.5	Poly HTA Acid	17 16 15	HC1 or Sulfamic HC1 or Sulfamic
ME	185 240	.033 2.16	Poly Acid	7 8	HC1 or Sulfamic
TC	150	.056	Poly	5.0	HC1 or Sulfamic
MVC	170 215	.034 2.04	Poly Acid	5.0 5.0	HC1 or Sulfamic
RO (30% recovery)	N/A	1.9	Acid	2.0	Ammoniated Citric PTB Formaldehyde Detergent

Table 9. Auxiliary Consumables

Conclusion

The purpose of this paper is to provide the user of seawater desalination equipment with a better understanding of the factors which are important to process evaluation and selection. No attempt has been made to give absolute costs for equipment, utilities or water because these figures vary widely and change frequently.

The evaluation of a process should involve the factors discussed; that is, maintenance, operating complexity, operating costs and capital cost. Each user must also analyze his particular situation taking into account product water use, quality of seawater, site location, installation cost and intangibles such as the quality of operating personnel and supervision.

Each process has advantages and disadvantages and the final process decision should be based on achieving the desired reliability while minimizing the unit cost of water.

ACKNOWLEDGMENT

The Authors wish to thank the executives of Aqua-Chem, Inc. for permission to present this paper and Kenneth Irwin, Philip Liu, William Peak and Susan Pues, whose assistance was invaluable in this preparation.

DESALINATION TECHNOLOGY

Report on the State of the Art

Submitted to the Metropolitan Water District of Southern California

Alfred N Rogers, Charles D. Siebenthal, Robert F Battel and
Leon Awerbach - Project Manager Bechtel Group, Inc. Feb 1983

BACKGROUND

SUMMARY

Large quantities of water are required throughout the United States for agricultural, industrial, and residential use. Providing the necessary water supply presents a problem in many cases, particularly in Southern California where the local water supply is inadequate to meet local needs. As a result, it has been necessary to import water into this area from distant sources.

Southern California has a large potential water supply in certain brackish groundwater basins and in the Pacific Ocean. These supplies have not been developed in the past because of the high cost of desalination compared to the cost of alternative sources. As water needs continue to grow, it will become increasingly expensive to develop new sources of imported water and desalination may become cost competitive.

This report has been prepared as a resource document for use by The Metropolitan Water District of Southern California in planning the District's present and future involvement in desalination projects. The report presents the current technical and economic status of alternative desalination processes for seawater, brackish water, and wastewater reclamation.

STATUS OF DESALINATION

It is now technically feasible to generate large volumes of water of suitable purity by the desalination of brackish water and seawater. During the past two decades, over 2.24 million acre-feet per year (Af/y) (2 billion gallons per day (gpd)) of desalination capacity has been installed throughout the world. Although there have been "growing pains," the plants, ranging up to 300,000 Af/y in one location and comprising single trains of over 11,200 Af/y (10 million gpd), have performed reliably, delivering water of high purity at a cost which is acceptable in the regions where the plants have been built.

On a worldwide basis, there are a very large number of small desalination plants serving hotels, condominiums, and small industrial establishments. Even if we limit the discussion to plants of 28 Af/y (25,000 gpd) capacity and larger, the present number of plants worldwide still exceeds 2,200. Figure 1-1 shows the distribution of this number of plants according to the size of the desalination plant. Notice that only 10 percent of the plants (those having capacities of 1,000 Af/y or larger) account for more than 80 percent of the world's installed capacity.

The large plants are required primarily in water-starved areas, where they are the primary source of supply. Figure 1-2 indicates that the greatest installed capacity is in the Middle East and North Africa. Since plants in the Middle East have capacities of up to 268,800 Af/y, it is not surprising that the Middle East accounts for two-thirds (66 percent) of the worldwide installed-plant capacity. The strong showing of Europe and the United States, two normally nonarid regions, indicates that *local* needs may exceed economically available water supplies even in such temperate regions, thereby justifying the use of desalination.

Figure 1-3 shows the wide diversity of processes currently employed for desalination. The predominance of multistage flash (MSF) plants is explained in part by the early use of MSF in Kuwait and subsequently in Saudi Arabia, after which these users issued repeat orders for a technology with

Figure 1-1 DESALTING PLANTS WORLDWIDE
(Grouped According to Plant Size)

Figure 1-2 DESALTING PLANTS WORLDWIDE
(Grouped According to Geography)

Figure 1-3 DESALTING PLANTS WORLDWIDE
(Grouped According to Type of Process)

which they were familiar. For the future, it is believed that multiple-effect distillation will supplant MSF plants due to better energy efficiency. Note in Figure 1-3 the increasing use of reverse osmosis (RO). This process is employed primarily for seawater desalination in plants less than 5,000 Af/y and desalting brackish water. Electrodialysis (ED) has historically competed with RO for brackish water desalting in the past but has been hindered by membrane fouling problems. Since introduction of the electrodialysis reversal (EDR) in the early 1970's, the ED process has to a large extent eliminated this problem making ED truly competitive with RO.

Figure 1-4 groups the world's desalination plants according to the type of feedwater. Most of the large-scale projects in the Middle East have used seawater, a practically limitless resource. The largest brackish water desalting project supplies the city of Riyadh, Saudi Arabia. The Wellton-Mohawk desalination project at Yuma, Arizona, now coming on stream, desalts 80,000 Af/y of agricultural return flows. The desalination of municipal and industrial wastewaters is a comparatively minor but expanding activity at present in the United States and other advanced countries.

Section 5

TECHNICAL COMPARISON OF PROCESSES

This section discusses a number of important technical considerations that should be involved in the selection of a desalination process. These considerations include:

- Purity of the product
- State of development of the process
- Insensitivity to feedwater total dissolved solids (TDS)
- Pretreatment requirements
- Necessary skill of operators
- Maintenance requirements
- Stability under design conditions
- Flexibility of the process
- Reliability of the process

PURITY OF THE PRODUCT

Any one of the distillation processes can produce comparatively pure water. Manufacturers typically submit bids containing warranties that the TDS will be less than 25 mg/l and, in some bids, less than 10 mg/l. The reverse osmosis (RO) membrane process, on the other hand, can attain about 500 mg/l from a seawater source in a single pass. From a brackish water source, a 90 percent reduction in TDS is commonly attained. Electrodialysis (ED) can perform about as well with a brackish feed but has not succeeded in desalting seawater on a commercial scale.

Equally important is the selectivity of the process for specific contaminants. It is apparent that at least a fraction of the volatile impurities will be carried over into the product by a distillation process. ED cannot remove from the feed any material that is not ionized. Consequently, the removal of silica is zero. RO, although not an electrolytic transport process, is sensitive to the ionic nature of the contaminants, removing more effectively those with a higher charge. Calcium (Ca^{++}) is removed far better than sodium (Na^{+}), and sulfate (SO_4^{--}) better than chloride (Cl^{-}). A nonionized material such as dissolved carbon dioxide (CO_2) or boric oxide (B_2O_3) is not removed at all; that is, its concentration in the permeate is identical to that of the feedwater. These specific contaminants can be ionized to a degree and, hence, partially removed by raising the feed pH; however, many membranes are sensitive to alkaline conditions and would disintegrate in a short time at a high pH.

Desalination by freezing results in almost pure ice crystals, but the adhering brine that is not removed by rinsing contributes impurities to the product. Contaminants are rejected regardless of ionic charge. Because of the low temperature of operation, many volatile impurities remain behind in the reject stream.

STATE OF DEVELOPMENT OF THE PROCESS

All of the variants of the distillation processes discussed in the preceding section are fully developed and have been in successful commercial use for a number of years. The membrane processes, RO and ED, have processed brackish waters in sizable modules for over 10 years; however, seawater ED is not

yet available. One seawater RO plant has been in operation for the past 6 years and another for 4 years, and a number are now coming on line. Freezing desalination, while yielding excellent results in pilot plant equipment, has yet to be installed in a moderately large, commercial plant.

Improvements continue to be made in all these processes. In distillation, the emphasis is largely on the reliability of components and the control of corrosion. (See the subsection, "Maintenance Requirements.") In membrane processes, the present effort centers on membrane reliability, new membranes, and on membrane sizing, a method of upgrading deteriorated membranes based on established textile sizing procedures.

INSENSITIVITY TO FEEDWATER TDS

Although the "minimum theoretical work" of distillation is roughly proportional to feed concentration, the total energy consumption is almost the same for seawater or very dilute brackish water. The membrane processes, on the other hand, experience a sharp increase in energy demand as the feedwater concentration rises. For RO, the pump pressure required by a brackish feedwater is 250 to 400 pounds per square inch (psig), for seawater 800 to 1,000 psig. The ion migration and other problems with ED are even more serious. Not only does the ED ion transport current increase with dissolved salt concentration, but a high salinity concentrate stream increases back-diffusion of solute, to a large extent negating the desalting action of the electric current. In addition, very high salinities short-circuit the current through the flow ports, thereby "burning" the edges of the membranes and the electrodes. These problems have tended to limit the application of ED to feedwaters of low TDS. In freezing desalination, increased salinity of the feed lowers the freezing point of the brine, thereby increasing the energy consumption. In addition, a high-salinity feedwater will yield a less pure product water than a feed of low salinity.

PRETREATMENT REQUIREMENTS

Large objects must be eliminated from any feedwater stream. To this end, ocean surface intakes are equipped with trash racks and screens. An alternative is the construction of sea wells, which strain the seawater through the naturally occurring sand of the seashore. These wells remove not only kelp and marine organisms but also fine suspended matter that cannot be tolerated by RO membranes. In contrast, distillation plants are indifferent to moderate amounts of silt. If the silt loading is excessive, its removal by means of hydrocyclones is adequate for distillation plants. For both RO and most distillation plants, it is mandatory to chlorinate the feed: preferably by shock chlorination, a treatment that destroys microorganisms and, in the case of open intakes, also the shellfish, which could lodge in the tubes of distillation plants, either blocking the flow or inducing erosion by generating eddies downstream from the obstruction. In general, this concern is minimal in those horizontal tube plants where the brine is sprayed on the outside of the tubes because deposits on the exterior of the tube do little harm and are easily removed.

The formation of scale can be a serious obstacle to the successful operation of a desalination plant. Scale deposits impose a barrier to the transfer of heat in a thermal process, coat and even pierce membranes in a membrane plant, and obstruct flow passages and "freeze" valves in any kind of plant. One of the most common scale formers is calcium carbonate ($CaCO_3$), which deposits when

carbon dioxide (CO_2) is released from the feed by boiling or by CO_2 transfer across a membrane, as described previously:

$$Ca(HCO_3)_2 \longrightarrow CO_2 + H_2O + CaCO_3$$

One of the oldest methods for the prevention of scale is the acidification of the feed with a mineral acid. This technique, however, requires the storage and handling of a potentially dangerous substance and, if not carefully controlled, may induce rapid corrosion of metallic plant components. Scale control additives have been tested for the prevention of carbonate scaling with varying degrees of success. For RO plants, the transfer of CO_2 across the membrane makes the use of acid in combination with additives the best method at present. For distillation processes that operate below 240F, high-temperature additives show promise. Multistage and multi-effect plants at temperatures not exceeding 195 F have successfully used sodium polyphosphate for a number of years.

Even plants using acid for the prevention of carbonate scale require sodium hexametaphosphate (SHMP) or one of the newer additives to prevent the deposition of calcium sulfate, a common problem in brackish water and all seawater.

RO, in general, requires thorough pretreatment to avoid deposits that might decrease the product flux or, in extreme cases, could completely destroy the membranes. Particular care in feed preparation is required when desalting surface or wastewaters (e.g., agricultural drains). As an example, the Yuma desalination plant of the U.S. Bureau of Reclamation incorporates the following pretreatment steps:

- Straining through a trash rack
- Chlorination
- De-silting in a settling basin
- Softening, coagulation, and settling in a reactor-clarifier
- Supplementary chlorination
- Filtration through a dual-media filter
- Dechlorination by passage though a bed of activated carbon or, preferably, by the addition of bisulfite
- pH adjustment with sulfuric acid
- Injection of anti-scalant additive
- Passage through a 5-micron or 10-micron cartridge filter

The RO plant of the Orange County Water District furnishes an example of an adequate process and careful operation that yields satisfactory results with a wastewater feed. There, a secondary sewage effluent is pretreated by softening, coagulation, activated carbon, and dual-media filtration prior to RO desalination. Successful operation has been reported.

For seawater, several of these steps may be omitted if the intake consists of sea wells or a Ranney well (a well terminating in a number of laterals).

Reports indicate that in contrast to RO, ED with reverse polarity can operate safely for extended periods without acids or additives. This is equally true for the freezing process. Silica, which deposits damaging scale from some feedwaters in other membrane processes, is reported to do no harm in ED plants with reverse polarity.

NECESSARY SKILL OF OPERATORS

At present, no operating experience is available for commercial-scale freezing desalination plants. The other processes discussed in Section 4 present a wide spectrum of requirements for operator education and training. At one end of the spectrum, reverse polarity ED, low-temperature multi-effect distillation, and low-temperature vapor compression require very little operator attention or skill. High-temperature distillation requires careful attention to scale control and corrosion prevention methods. The most demanding process is RO, for which operators must be trained in all the pretreatment steps. A dedicated and skillful crew is necessary to ensure satisfactory RO plant performance. Ignorance or indifference can result in the catastrophic failure of any process.

MAINTENANCE REQUIREMENTS

In every well-operated plant, even those which inject acid into the feed stream, scale and other contaminants will deposit slowly. When the heat transfer drops below a predetermined value in a distillation plant or when the product flux or purity drops to a preset value in a membrane plant, cleaning as outlined below is initiated:

- In distillation plants, inhibited acid is circulated through the system. This can be done without shutdown, but with no water production. A high-temperature system will require cleaning at intervals of 3 to 6 months, provided no serious maloperation has occurred. A low-temperature plant must be cleaned at intervals of 6 months to 2 years. In an MSF plant, the scaling rate can be substantially reduced by continually circulating sponge balls through the tubes during plant operation, a process that involves an increase in investment.
- For an RO system, a detergent/suspending agent solution is circulated through the feed side of the plant. If the elements are loaded with scale to the point that the cleaning process is ineffective, the elements must be removed from their pressure vessels and soaked in a tank of cleaning solution. Should this fail to solve the problem, the membrane elements must be discarded and replaced by new ones.
- Although polarity reversal is quite effective in eliminating scale formation in ED, either deposits on the membranes or other problems may require maintenance. Prior to shutdown, the trouble spots are located by measurement of inter-cell potential drop. Then the stack is disassembled and dirty membranes are cleaned by manual scrubbing. Membranes showing burns or fractures are replaced. Defective electrodes are removed for replating.

Should an RO system exhibit an increase in flux accompanied by a drop in product purity, there is reason to suspect local imperfections in one or more membranes. The maintenance procedure consists of circulating a sizing solution of a composition determined by the membrane material. The sizing solution fills the microscopic voids and, if successful, permits the continued use of the membrane.

The maintenance of an RO pretreatment system requires specialized skills because of the numerous and intricate subsystems involved. The most troublesome one from the standpoint of corrosion is the acid injection section where the localized dilution of a strong acid occurs. Maintenance in this area can be held to a minimum by constructing the in-line mixer and the mixing pipe spool of high-alloy materials. The RO vessels themselves are seldom a problem since they are constructed of stainless steel or fiber-reinforced plastic; however, connectors to the elements have experienced corrosion and maintenance problems, requiring upgrading to high-nickel stainless steel.

In contrast, the shells and internals of high-temperature distillation plants may corrode rapidly unless constructed of, or clad with, corrosion-resistant alloys. Heat transfer tubing may also be a source of serious trouble. Even the more costly alloys, such as aluminum-brass, copper-nickel and titanium and its alloys, may have a comparatively short life under some conditions of operation. Maintenance consists of welding "patches" on the vessel and plugging or replacing defective tubes, both operations requiring equipment shutdown and the use of skilled laborers. Where low-temperature distillation is used, however, corrosion is almost eliminated. The carbon steel vessels are protected by a multilayer internal coating of cured organic material. The heat transfer surface is formed from Alloy 5052, a seawater-resistant alloy of aluminum. Should a perforation occur in a tube of a low-temperature multi-effect distillation plant, there is no effect on product purity since the pressure on the product side is greater than that on the brine side. In all processes, maintenance is required on pumps and rotating equipment.

STABILITY UNDER DESIGN CONDITIONS

All the desalination processes described in this report are quite stable under design conditions. Two possible sources of instability are the vapor compressor in a VC plant and the control equipment in any desalination plant. It is safe to assume that a reliable manufacturer of vapor compression equipment will design a compressor to operate in the stable range. The balance of this or any other system can become unstable if the control system exhibits positive feedback characteristics. The most annoying (and perhaps damaging) is the improper control of flow in a circulating loop, resulting in surging, but this is seldom a problem in a well-designed control system.

FLEXIBILITY OF THE PROCESS

The purchaser of a desalination plant will ask two questions:

- Can I achieve more than the rated output if needed?
- To what degree can I cut back on the plant production?

As for the first question, it must be remembered that the supplier is not obligated to provide overcapacity beyond the contracted value. However, it is possible to increase the output of an ED cell simply by increasing the current through the cell, making certain not to exceed the maximum specified by the manufacturer. For an RO plant, an increase in applied pressure, if permitted by the pumps, will yield a greater product flow, but at the expense of shortened useful membrane life. The output of a VC plant can be increased only if the compressor motor and the compressor itself have been overdesigned. A higher output from a thermal distillation plant requires an increase in prime steam tem-

perature and flow, preferably with an increase in brine recirculation rate. A higher steam temperature increases the danger of scale formation in the prime heater, even if the pumps permit an increase in recirculation rate. In summary, a 10 percent increase is possible for MSF, 25 percent for MED; a substantial production increase in the other processes is questionable.

The answer to the second question depends on the desalination process. For ED, unlimited turndown is possible, accompanied by an improvement in product purity, but an increase in specific energy consumption. Alternatively, an ED plant can be turned on and off, as needed, with no harmful effects. For RO, on the other hand, a decreased feed pressure cuts down product flow but is detrimental to product purity. In addition, there are definite limits to minimum and maximum flow through RO elements. Turndown of a VC plant lowers the energy efficiency and, even more seriously, may lead to instability of the compressor. MSF can tolerate, in general, a turndown of about 10 percent, below which the operation becomes unstable or ceases to function entirely. Multi-effect distillation (MED) output can be reduced substantially without instability or energy penalty, except for the wasted power of the recirculating pumps. It has been demonstrated that the multi-effect evaporator design can readily accept a 40 to 45 percent turndown, which is achieved rapidly in response to changes in the steam supply. When a desalination plant is built using a number of modules, as is sometimes done for increased reliability and flexibility, one or more modules may be shut down as the need dictates. A prolonged shutdown, however, requires precautionary measures. An unlined carbon steel plant, such as those frequently used in distillation processes, requires nitrogen blanketing, together with the addition of an oxygen scavenger to the brine to minimize corrosion of the steel. For an RO plant, a protracted shutdown requires that the brine in the system be replaced with product water containing a bacteriostat such as formaldehyde.

RELIABILITY OF THE PROCESS

Each of the desalination processes reviewed in this report must be considered as a system that includes the requisite pretreatment steps. Any interruptions attributable to problems with pretreatment will affect the reliability of the entire system. On this basis, the most dependable desalination processes are the ones requiring the fewest and simplest pretreatment steps. From the standpoint of interruptions of the desalination process due to the pretreatment train, the most-serious problems can be anticipated from RO as applied to surface waters and wastewaters (although RO brackish water plants have generally performed well). On the other hand, the processes requiring the simplest pretreatment and, hence, exhibiting the greatest reliability are reverse polarity electrodialysis and low-temperature distillation. The reliability of each of the three broad categories of commercial desalination processes is evaluated below.

Distillation Processes

Serious problems have been encountered in multistage flash plants, particularly those operating with pH control of scale. Operator inattention or defective instrumentation has been responsible for wide swings in pH. Insufficient dosage of acid permits scale deposition, and excess acid leads to catastrophic corrosion of tubes and evaporator shells. Even a well-operated plant is difficult to control since the target pH is on the knee of the pH-vs-dosage curve. One alternative for good scale control with moderate corrosion is the injection of scale control additives. Another source of difficulty is the chlorination required as biocide. The chlorine reacts with the bromides in seawater, liberating bro-

mine, which severely corrodes the venting system. Successful removal of both scale and marine organisms from heat exchange tubing has been achieved by circulating sponge balls through the plant (the Taprogge process), but at considerable increase in complexity and plant investment. Further corrosion problems are introduced by hydrogen sulfide (H_2S), which results from organics present in some seawater sources. Shutdowns for the repair of corrosion damage are frequent and become increasingly so with time.

Greater reliability is exhibited by the low-temperature distillation plants, both VC and multi-effect. Although still faced with the problems of marine growths, they suffer less from corrosion, and scale formation is easily controlled. In contrast with the high-temperature distillation plants, these low-temperature systems have been reported to operate from 6 months to 2 years before a short interruption for on-line cleaning is necessary. For the plants that operate at lower temperatures, an organic coating applied to the chamber interiors provides long-term protection to carbon steel. Multi-effect plants tubed with aluminum-alloy heat-transfer tubing experience a uniform tube corrosion rate of about 0.5 mil per year and show no sign of crevice corrosion or stress corrosion cracking even in the presence of considerable amounts of H_2S. Thus, almost no operating time is lost for retubing or for the patching of vessel shells.

The RO Process

For the RO process, the estimate of reliability is dependent on the type of feed. In general, plants supplied with brackish well water have an excellent on-stream factor if properly operated and serviced. Seawater plants have experienced a number of interruptions; however, the seawater application is relatively new, and its problems are expected to be gradually solved. At the other extreme, a high degree of reliability cannot be predicted at this time for the processing of surface waters or wastewaters by RO unless very thorough pretreatment is provided.

The ED Process

Improvements are being made in all desalination processes. In ED, the early problems of scaling and attack on the electrodes have been overcome by the introduction of reversing polarity. (See Section 4.) Recent plants using reverse polarity ED for the desalination of brackish water are performing well and exhibit a satisfactory on-stream factor. It should be emphasized again that ED is not currently offered for seawater desalination and that its reliable application to wastewaters requires careful attention to the control of bacteria and membrane contaminants such as iron in solution.

SUMMARY OF THE TECHNICAL COMPARISON OF PROCESSES

Table 5-1 summarizes the evaluation discussed in the preceding subsections. Under each criterion, a number has been assigned to represent the rating of each process as follows: 3 — a highly satisfactory process; 2 — a process that is only fair in meeting a particular criterion; 1 — a process that does not perform well or one that is troublesome; 0 — a criterion that has not yet been demonstrated for the particular process.

A rating system covering a wider range of grades, for example, 0 to 10, does not appear to be justified because of the difficulty of breaking down each criterion into finer degrees of performance.

Table 5-1

TECHNICAL COMPARISON OF PROCESSES

Process	Purity of the Product	State of Development	Insensitivity To Dissolved Solids of Feed	Pretreatment Requirements	Necessary Skill of Operators	Maintenance Requirement	Stability Under Design Conditions	Flexibility	Reliability of the Processes	Sum of Ratings
Multi-stage flash distillation (seawater only)[a]	1	3	3	2	2	1	3	1	2	20
Multi-effect distillation (seawater only)										
Vertical tube, high temp[a]	1	2	3	1	2	1	3	1	2	20
Horizontal tube, low temp[a,b]	3	2	3	3	3	2	3	3	2	24
Vapor compression distillation[c]	3	3	2	2	2	2	3	2	1	22
Reverse osmosis										
Seawater	2	2	2	2	2	3	3	3	2	21
Brackish well water	2	3	1	2	2	3	3	3	1	22
Surface or wastewater	2	2	1	1	1	1	3	3	1	15
Freezing desalination[d]	1	0	3	3	0	0	0	0	0	7
Electrodialysis										
Seawater	Not currently available for seawater desalination									
Brackish water or wastewater	2	3	2	2	3	2	3	3	1	21

Ratings:
- 1 - Highly satisfactory process
- 2 - Fair
- 3 - Low quality or troublesome
- 0 - Performance not demonstrated

Notes
(a) Not competitive for brackish water.
(b) Technically superior to membrane process for some wastewaters
(c) Large units sold predominantly for wastewater concentration.
(d) Pilot plant tested on seawater and some industrial concentration processes to date

The sum of the ratings for each process provides a basis for selection by the prospective purchaser. It has been assumed that each of the technical considerations is weighted equally. Under some circumstances, the purchaser of a desalination plant may be justified in attaching greater importance to one or more of these criteria, leading to a different ranking of the processes than the one shown here. The reader should note that a zero rating does not indicate a failure but, instead, that the process has not yet advanced beyond the pilot plant stage. In addition, commercial ED has not been developed for seawater desalination. Freezing and seawater ED, however, may be considered for future development.

It is apparent that a process may have a high rating for some applications and yet be a questionable choice for others. For example, Table 5-1 shows that RO merits serious consideration for the desalination of brackish well water but may encounter troublesome problems in the treatment of some surface waters or wastewaters. In general, the highest overall rating is shown for seawater desalination by multi-effect distillation in low-temperature plants of the horizontal tube type.

In some applications, the use of a process of slightly inferior numerical rating but lower overall cost may be justified. (See the discussion of economics in Section 6.)

Section 6

ECONOMIC COMPARISON OF PROCESSES

This section first develops a generalized estimate of the investment required for each type of process. The base case involves a plant to yield 5,000 to 6,000 acre-ft/yr (Af/y) of desalinated water. For each process, the cost of the product water is then estimated including major cost components:

- Capital
- Energy
- Operation and maintenance (including applicable G&A)
- Chemicals and general supplies
- Membrane replacement (reverse osmosis and electrodialysis only)
- Filter replacement (where used)

The capital investment estimates are based on a review of current studies in the desalting field and recent awards for actual plants. The costs include minimum allowances for site-specific items, but no particular site has been assumed. The desalting plants do not include a boiler for thermal processes that require steam heating. Steam requirements are handled as a utility — part of the operating costs.

The basis for the estimates of the cost of water is as follows:

- Plant life — 20 years
- Interest rate — 10 percent
- Insurance — 2 percent
- Cost of electricity — $0.06/kWh

The designations "single-purpose" and "dual-purpose" reflect the source of steam for the thermal processes. The cost of steam for a single-purpose plant is assumed to be $6/million Btu, representative of costs incurred in generating steam by burning an oil fuel. For a dual-purpose plant, where steam is extracted from a nearby steam-electric power generating facility, the costs range from $2.50/million Btu for steam at 50 psia (about 280F) to $0.32/million Btu for steam at a pressure of 5.5 inches of mercury (about 130F).

Both capital investment and cost of water estimates are intended as comparative costs among themselves and should be used only to determine cost trends. For a specific project where the site and the feedwater have been identified, the cost of produced water may vary considerably from those presented here. A site-specific analysis could result in a change in the relative ranking of some of the processes. The final choice of a process will depend upon those items mentioned above as well as the energy availability and cost at the time, the economic climate, the projected inflation rates for various categories of costs, and the social, legal, and environmental constraints at the proposed plant site.

In developing estimates of water costs, the annual water production was reduced from the daily design capacity to account for plant downtime. The stream factor (percentage of time the plant is running) for the processes considered ranges from 75 to 95 percent. Table 6-1 lists the estimated stream factors for each process and feedwater. The provision of storage facilities may be important for isolated facilities. For a large, flexible system such as the Metropolitan Water District and associated

agencies, it does not appear to be necessary and, consequently, the cost of storage tanks was neglected in this report.

Tables 6-2 and 6-3 summarize the capital investment requirements for seawater and brackish/wastewater desalting plants. The costs are presented as unit investments, i.e., dollars per Af/y plant capacity, for a plant in the size range of 5,000 to 6,000 Af/y. These costs are also presented in the form of bar charts in Figures 6-1 and 6-2.

Table 6-1

STREAM FACTOR ASSUMED FOR EACH PROCESS

Plant Type	Feed	Stream Factor (Percent)
Multistage flash	Seawater, acidified	75
Multi-effect vertical tube	Seawater, acidified	85
Multi-effect horizontal tube, low temperature	Seawater, no acid	95
Multi-effect horizontal tube	Wastewater	95
Vapor compression, low temperature	Seawater, no acid	95
Vapor compression	Wastewater	85
Reverse osmosis	Seawater	85
	Brackish water	92
	Wastewater	85
Electrodialysis	Brackish water	95

Table 6-2

COMPARATIVE INVESTMENTS FOR SEAWATER DESALINATION PLANTS

(5,000 to 6,000 Af/y Capacity) (6 × 10⁶ m³/year

(AF - 20,999 m³/day)

Plant Type	$/Af/y (4th Quarter 1982)
Single-Purpose Plants	
Multistage flash[a]	6,700
Multi-effect vertical tube[a]	5,900
Vapor compression, low temperature[b]	4,200
Reverse osmosis:	
1-pass hollow fine fiber	3,300
2-pass spiral wound	3,600
Dual-Purpose Plants	
Multi-effect flash[a]	6,700
Multi-effect:	
Vertical tube[a]	5,900
Horizontal tube[c]	5,100
Horizontal tube, low temperature[d]	4,600

(a) Performance ratio of 12 (see Sect. 3), acid added, steam temperature = 250F

(b) Low energy use (38 kWh, 1,000 gal). ~10 kwh/m³

(c) Performance ratio of 6, no acid, steam temperature = 180F

(d) Performance ratio of 2.85, no acid, steam temperature = 135F

Table 6-3

COMPARATIVE INVESTMENTS FOR BRACKISH WATER DESALINATION PLANTS
(5,000 to 6,000 Af/y Capacity)

Plant Type	$/Af/y (4th Quarter 1982)
Brackish Water Feed	
Reverse osmosis	760
Electrodialysis:	
2,000 mg/l feed	1,300
3,500 mg/l feed	1,750
Wastewater Feed	
Reverse osmosis[a]	940
Vapor compression[b]	4,400
Multi-effect horizontal tube, low temperature[a]	4,400

(a) For municipal wastewater.

(b) For cooling tower blowdown (industrial wastewater) concentration.

It is apparent that for seawater, the lowest plant investment is represented by the reverse osmosis (RO) process using either hollow fibers or the spiral wound configuration. This is equally true for brackish water. For the latter, electrodialysis (ED) is a close second, its investment cost depending on the salinity of the feed.

The costs of producing water, expressed as $/Af, are shown in Table 6-4 with a breakdown of three categories of costs — (annualized) capital, energy, and other (including labor, operating supplies, and maintenance materials). Table 6-4 indicates that for a single-purpose plant supplied with a seawater feed, the lowest cost of product water is achieved by the high-efficiency low temperature vapor-compression plant. When the supply is brackish water, however, the lowest water cost is achieved by either ED or RO. As in the case of plant investment, product cost from ED is influenced by the composition of the feed as shown by the difference in water costs for 2,000 and 3,500 mg/l wellwater.

The effect of energy cost is shown clearly by the economic advantage of coupling a distillation plant with a power plant in a dual-purpose plant. This can be seen by comparing the single- and dual-purpose plant costs in Table 6-4 for multistage flash and multiple-effect vertical-tube plants. In the case of seawater desalination, the lowest overall cost is achieved by coupling a multi-effect horizontal low-temperature desalter with a power plant. The heat that would normally be rejected to the power plant condenser provides a low-cost source of energy for desalination.

The contribution of each of the major cost components to the product water cost is summarized in Table 6-4, and is presented in Figures 6-3 through 6-10 inclusive for seawater feed, and Figures 6-11 through 6-16 inclusive for brackish water and wastewater. These cost components are for a plant size

(e) Steam cost ranges from $2.50/million Btu to $0.32/million Btu

(f) Municipal wastewater feed

(g) Industrial wastewater (cooling tower blowdown) feed

of 5,000 to 6,000 Af/y. It is important to note that the value of the energy consumed is one of the major contributors to overall product cost.

To minimize the energy cost for the reverse osmosis plants, it is assumed that energy recovery is incorporated into the desalting plant. Energy recovery has not been assumed for the lower pressure brackish water plants, however, since the increased capital charges resulting from energy recovery equipment negates the savings in energy cost.

The plant investment and water costs discussed above are based on a plant of nominal 5,000-6,000 Af/y capacity. The economy of size is indicated by the data in Table 6-5, which shows unit plant costs for plants of 1,000, 5,000, and 12,000 Af/y. For each technology, the plant cost per Af/y of plant capacity tends toward a constant value as plant size increases, since desalination plants are of modular construction and a single desalination complex of large size is composed of a number of modules of smaller size. For example, for membrane plants, the individual modules may be as low as 100 Af/y, even for large installations. Distillation plants seldom exceed 7,000 Af/y in a single train. The largest commercial vapor compression distillation plant produces 970 Af/y.

EFFECT OF BLENDING

One of the ground rules of this study was that the economics section should list the cost of water as produced and that MWD would calculate the cost of the blended product if such blending were desirable. Figure 6-17 is included to assist the reader in adjusting the water cost to allow for blending. For example, if a well water with 2,000 mg/l of dissolved solids is available, distillation product water at 10 mg/l can be blended to a 500 mg/l at a 25 percent reduction in the cost of distilled water product. An additional benefit of blending is the corresponding increase in usable water delivered by the plant. Thus, in the example cited above, a 5,600 Af/y desalination plant will deliver 7,400 Af/y of blended water containing 500 mg/l of total dissolved solids. Figure 6-17 permits cost calculations also for blending product waters of several other purities.

Table 6-5

ESTIMATED EFFECT OF PLANT CAPACITY ON COST OF PRODUCED WATER

Process	Cost of Produced Water Relative to Production Cost from 5,000 Af/y Plant		
	1,000 Af/y	5,000 Af/y	10,000 Af/y
All seawater processes	1.40-1.50	1.00	.85-.90
Brackish water processes			
RO and low-temperature multi-effect horizontal tube	1.30-1.35	1.00	.90-.95
EDR (electrodialysis reversal)	1.80-1.90	1.00	.85-.95

SEEDED SLURRY REVERSE OSMOSIS

AND

SEEDED SLURRY EVAPORATION

PRESENTED

AT

THE RANDOL WATER WORKSHOP

OCTOBER 21-23, 1984

R. Reams Goodloe, Jr.
Resources Conservation Co.
Bellevue, Washington
U.S.A.

I. "SEEDED" PROCESSES FOR CONCENTRATION OF AQUEOUS SOLUTIONS

The concentration of solutions containing low solubility salts is aggravated by the occurance of scale forming compounds in the solution being treated, whether in an evaporation based, or in a membrane process based, or a combination treatment plant. Although the solubility limits for many species commonly present in wastewaters can be slightly exceeded by use of additives such as dispersants or crystal modifiers, the practical effect of the presence of scale formers in process waters has been to either live with the scale (typically possible only in evaporation or electrodialysis reversal), or to design the system for normal operation below expected solubility limits of species present. In the majority of industrial wastewater processing applications, either alternative is not a desirable choice, since additional operating costs are involved for cleaning, or additional water recovery is not easily achieved.

Resources Conservation Company, of Bellevue, Washington, has developed a proprietary process to effectively control seeding parameters in evaporation equipment, and a patented process to effectively control seeding parameters in membrane equipment, to allow concentration of solutions many concentration factors beyond the solubility limits of commonly found scale forming compounds. Both processes are based on the widely known but less widely understood process of providing a more extensive and more favorable surface for scale deposition than the heating or membrane surface itself. Seed crystals of the scale forming ingredients themselves typically provide the most favorable surface for deposition of potential scale. Since calcium sulfate and silica are the most commonly encountered scale formers, RCC has used calcium sulfate as the base for co-precipitation of itself and other species when concentrating solutions. In evaporation systems, calcium sulfate is commonly found in the anhydrite form at the temperatures found in the equipment, and in membrane systems, calcium sulfate is found in the gypsum form.

RCC provided evaporation units incorporating this technology have been operating for more than ten years, with more units being added every year to the operating inventory. Operators have found that sustained scale free operation is possible, with equipment downtime for routine maintenance normally once every 10 to 18 months.

RCC has been developing the laboratory, pilot plant, and field testing data on seeding for membrane processes, in particular for use with reverse osmosis, for more than seven years. Currently known information on process parameters, and ongoing improvements in membrane technology, have given RCC the confidence to offer the seeded reverse osmosis (SRO) technology to potential users.

Since the technical risks of this new process can be minimized by on-site testing using currently available test modules, we expect to see commercial installations very shortly.

The RCC Brine Concentrator

- CONCENTRATES HIGH SALINITY BRINES MANY TIMES BEYOND $CaSO_4$ & SiO_2 SOLUBILITY LIMITS TO MINIMIZE WASTE VOLUMES
- PREVENTS SCALE FORMATION WITH SEED SLURRY PROCESS
- PRODUCES HIGH QUALITY DISTILLATE
- USES VERTICAL TUBE, FALLING FILM EVAPORATION SYSTEMS TO PREVENT DRY SPOTS ON HEAT TRANSFER SURFACE
- AVAILABLE IN EITHER VAPOR COMPRESSION OR MULTIPLE EFFECT CONFIGURATIONS

Brine Concentrator

Typical Input/Output Compositions

The RCC system controls scale.

The vapor compression evaporator employs a new seed-slurry technique to control scale. In essence it forces scaling material to build up on crystals in the brine instead of allowing it to cling to the tube walls as scale.

Brine Concentrator Flow Schematic

④

DESIGN & EQUIPMENT

Brine Concentrator

- Cooling Tower Blowdown
  - Can Recover 99% Of Waste As Product Water
  - Product Water Less Than 5 mg/l TDS
  - Insensitive To Changing Chemistry
  - Simple, Automatic Operation
  - Many Installations With Similar Feedwaters
  - Energy Use Less Than 21 KWH/m^3
  - Scale Free Operation
  - High Availability Proven
  - 30 + Year Lifetime Established
- Demineralizer Wastes
  - Can Process To Approximately 90% Recovery
  - Minor Chemical Addition Required. (Calcium)
  - Ammonia Stripping Necessary For Highest Purity Product

RCC Evaporator Design Features

- Potential for Scaling and Fouling is Minimized
  - High Liquor Velocities in Critical Areas
  - Flow Distributors to Insure That All Tubes Are Completely Filmed
  - Proper Recirculation Rates to Insure Filmed Tubes and Low Extraction Rates
  - Effective Entrainment and Foam Control to Prevent Carryover (No Steam Side Fouling)
- Control System Eliminates Risk of Overshooting or Undershooting Desired Final Concentration
  - Reduces Evaporator Fouling (Sometimes Caused by Over Concentration)
  - Reduces Steam Consumption in Subsequent Operations (Often Caused by Low Product Solids)
- Compressor Installation Details Lead to Reliable Operating Performance
- Computerized Plant Evaluations Allow Optimum Selection of Components to Provide Stable Operating Conditions at Low Energy Consumption Rates

FIELD TESTING CONCLUSIONS

- SRO CONCEPT VERIFIED FOR UNTREATED MINE DRAINANGE WATER
- 1.5 YEARS OF NON-SCALING OPERATION ACHIEVED
- MEMBRANES TOLERANT OF PARTICULATES AND COLLOIDAL MATERIAL
- SIGNIFICANT QUANTITIES OF METALS DID NOT AFFECT UNIT PERFORMANCE
- UNIT CAN BE OPERATED SUCCESSFULLY BY PERSONNEL INEXPERIENCED WITH RO
- RECOVERY OF 95% OF FEEDWATER CAN BE ACHIEVED

SRO REJECT SAMPLES SHOWING
RAPID SETTLING OF SLURRY

CONCLUSIONS

- SEEDED RO IS A TECHNICALLY FEASIBLE AND PILOT-PLANT-PROVEN TREATMENT FOR WATERS SATURATED WITH CALCIUM SULFATE.
- SRO IS MORE RELIABLE AND EASIER TO OPERATE THAN CONVENTIONAL RO WITH SOFTENING:
  - MINIMAL RELIANCE ON CHEMICAL SUPPLY
  - EASIER ADAPTATION TO FEED CHEMISTRY CHANGES
  - NO OPERATION OF SOFTENER SYSTEM
- ECONOMIC ANALYSIS INDICATES THAT –
  - SRO CAPITAL COST IS SUBSTANTIALLY LESS THAN CONVENTIONAL SYSTEM WITH PRETREATMENT, RO, AND EVAPORATION
  - SRO OPERATING COSTS ARE SUBSTANTIALLY LESS THAN CONVENTIONAL SYSTEMS WITH PRETREATMENT, RO, AND EVAPORATION

CHAPTER 21

DISPOSAL OF DESALINATION CONCENTRATE STREAMS

INTRODUCTION

Every desalination process produces a low TDS water product and a waste brine containing, in a concentrated form, the dissolved solids that were removed from the feedwater to make the desalinated product. In the case of ion exchange desalination processes, the concentrate may contain additional amounts of chemicals added to regenerate the loaded resin, although HENDRY (1983) has made a valiant attempt to show that this need not always be the case.

SCHUTTE (1983) summarized brine disposal alternatives, and Chapter 10 of his report is summarized below. It is clear, however, that each alternative is carefully qualified with one or more potential problems that must be avoided without saying how to avoid them.

Brine disposal remains an open questionmark in the U.S.A. today, although deep well disposal is a commonly practiced method for these and chemical industry wastes. However, very little has been written about desalination concentrate disposal. Regretably, virtually no cost data could be developed.

WATER RECOVERY

The water recovered by desalination processes is expressed as a percentage of the volume of feedwater. Water recoveries can be higher than 95% or lower than 25% resulting in brine volumes of less than 5% or more than 75% of the feedwater depending on the process employed, characteristics of the feedwater, and the goals of the desalination plant.

The most important factor which determines water recovery is the presence of scale-forming substances in the feedwater such as calcium carbonate, magnesium hydroxide, and calcium sulfate. When concentrations of these substances exceed their solubility limits as a result of the removal of pure water product, precipitation and scale formation results which usually seriously reduces the performance of the process. For this reason, feedwater is pretreated to remove these ions or to prevent them from precipitating by means of acid treatment, applying scale inhibitors or softening. In most desalination cases, however, especially those containing significant amounts of calcium sulfate, the only answer is to operate within the solubility limits of the compound. Even when scale inhibition is successfully applied, in almost all cases, the volume of brine may be reduced, but its concentration increases.

The seeded slurry reverse osmosis and seeded slurry evaporation processes are the only ways identified so far to avoid scaling and to enhance recovery while reducing the volume of brines yielding manageable solid precipitates in slurry form.

Water recovery in the desalination of seawater by reverse osmosis typically deteriorates from about 30% in newly installed modules to 20% for plants in which the membranes are approaching the end of their useful life. In distillation processes, water recoveries vary in the range of 40% to 60% for seawater feed.

Much higher recoveries are possible in the desalination of brackish waters where recoveries of 75% to 90% are typical and with seeded slurry R.O., a much higher recovery still, in the range of 95% plus can be achieved.

METHODS OF DISPOSAL

1) Sea Disposal

In coastal areas, disposal of brines does not present serious problems as they can be discharged to the ocean. However, that will be so only for brines generated by sea water desalination and where there are no toxic chemical or contaminants in the brines. Desalination of mine water or a mill effluent could well result in toxic brines that are not suitable for marine discharge--at least without further treatment. In any case, most mines are too far from the sea for this to practical in the first place.

2) Evaporation

In areas where there is a high net rate of evaporation such as in the dry parts of South Africa and the western interior of the U.S.A., disposal of effluents in evaporation ponds is the most cost-effective way of disposal. Where land costs are high, other methods may prove more cost effective. In the U.S.A., very often lined ponds are required which are expensive to install. Care must be taken to prevent seepage to groundwater aquifers and overflow or runoff to surface sources of water. In some cases, soil and subsurface conditions make a naturally impermeable pond floor. However, there are cases where evaporation ponds function better than theoretical evaporation rates would indicate because of invisible seepage. Many of these will be outlawed in the future and could cause problems with regulators.

In designing evaporation ponds that are lined, great care must be taken. The trip report on QUIVIRA MINING in Appendix I illustrates some of the unexpected problems that arise with lined evaporation ponds. Industry is still low on the learning curve in this area, and much care must be taken in the selection of lining material as well as the way it is applied. Consideration must also be given to the ultimate closure of the evaporation pond site in a stabilized way so that, in years to come, the concentrated salts cannot find their way into the environment.

3) Return to the Water Supply

Where boiler feedwater containing extremely low levels of dissolved salt is required and where available regional water is in short supply but relative low in TDS, then it is possible to use the regional water supply to recover say 10%-20% desalinated water and to return the "concentrate" which will have only 10%-20% higher TDS load than feed to the plant back to the regional water supply to be blended back with water supplied for other domestic or industrial uses. It is believed that the Electricity Supply Commission may apply this principle to some of their boiler feedwater treatment plant "concentrates." This is a very logical approach considering water conservation benefits and the avoidance of the need to dispose of brines. However, it has limited application in the tretment of mine-mill effluents.

4) Salt Water Sinks

In areas where large volumes of brine must be disposed of, the creation of a salt water environment in natural or artificial salt pans could greatly facilitate idsposal. This apparently is one of the alternatives under consideration for the disposal of brines from all kinds of desalination projects in the greater Witwatersrand area where there are major growing incentives to reduce the salt load in streams reaching the Vaal Dam.

5) Deep Well Injection

Brines are injected in wells to aquifers or rockstrata that are much deeper than any water source in the area to prevent any possibility of pollution. This a commonly used practice of the chemical industry in the United States.

In South Africa, deep defunct mines might be considered as a repository for brines provided contamination of underground waters could be avoided and provided that the old mine areas could be sealed to prevent brine flowing to active mines which are being dewatered, or where high salt content would enhance corrosion or cause other problems.

6) Further Processing

Further processing of brines in evaporator-crystalizers followed by spray drying producing a dry product is the recommended way of disposing of brines from desalination of many industrial effluents. At Rustenburg Refiners, a salable Na_2SO_4 product is produced which solves their brine disposal problem at the metallurgical plantsite.

7) Landfill Disposal of Solids

The seeded slurry reverse osmosis and evaporation processes yield brine slurries carrying crystalline precipitated salts which can be decanted easily to yield a "spadable" product for compact disposal. It was still too early to determine whether the precipitates in the seeded slurry R.O. process generated at ERPM (see trip

report in Appendix I for analysis) would pass the EP leach test for "hazardous" waste determination in the U.S.A. However, more information on this process can be requested from:

CHAPTER 22

APPLICATION OF DESALINATION AS A CONCENTRATING DEVICE IN EXTRACTIVE METALLURGY

Desalination techniques are not in use on any commercial scale operations as concentrating devices for metal values, except for some overlap in the use of ion exchange in selective metal recovery, for example, for uranium recovery.

It is believed that as membranes and system technologies are improved and particularly as effluent discharge regulations become more restrictive, there may be room for innovative applications of desalination techniques in resource recovery flowsheets. Removal or destruction of a pound of reagent costs a lot more than adding it to a solution in most cases. Therefore, methods to recover reagents may become sought after, just as in the case of metal finishing industries.

Potential applications for membrane technologies have been identified in two areas:

1) Recovery of Reagents in Reusable Form
2) Preconcentration of Metal Ions Before Recovery

RECOVERY OF REAGENTS IN REUSABLE FORM

- Various workers have experimented with the use of ED, for example, to recover reagent ions from spent solutions after the recovery of metal values in metallurgical processes. It is believed that the Council for Mineral Technology, MINTEK, in South Africa examined ED as a way of recovering sulfuric acid and ammonium hydroxide from spent metallurgical solutions containing ammonium sulfate. This research is either still in progress or has been terminated--no open file report on a successful process has been released.

- The magazine Galvanotechnik in West Germany described the application by a company, Linnhoff GmbH, of ED for the recovery of electrolyte from rinsewater in the metal finishing industry. In this process, 25 l/h of copper cyanide solution is recovered and returned to the plating bath from rinsewater containing 0.69 g/l Cu^{2+} and 0.34 g/l CN^{-}.

LINNEHOFF GmbH
Muhlenweg 15
D5870 Hemer
West Germany

- At an Australian nickel project that wishes to remain anonymous, high pressure reverse osmosis is used to upgrade $(NH_4)_2 SO_4$ from 10 g/l to 120 g/l in an effluent following ammoniacal leach at pH 5. Ultimately, a $(NH_4)_2 SO_4$ concentrated solution is generated which is disposed of as fertilizer. The company concerned declined to provide details on the R.O. system used and indicated a preference that the existence of the ammonium sulfate effluent be forgotten.

- Albany International has developed innovative new reverse osmosis membranes that allow ammonia to pass through readily while retaining base metal amine complexes which can be concentrated by a factor of 4-5 times in pregnant solution.

A copy of a draft evaluation of the benefits of using R.O. in the Sherritt-Gordon copper-nickel leading/precipitation process is inserted below. Although the assumptions and data are not refined, the concept appears intelligent. Randol International Ltd. believes that the new chemically resistant membranes developed by Albany International, if applied in tubular R.O. systems, would possibly be more appropriate as these avoid the possible need for filtration of solutions fed to the R.O. unit to avoid fouling by suspended solids. The albany International Ltd. membrane materials, however, allow a much wider operating pH range and are not as sensitive to high temperatures or Cl_2.

SEALED CELL ELECTRODIALYSIS

At the world conference on desalination held in Venice in May, 1983, ORA Kedem of the Weizmann Institute demonstrated a bench-scale sealed cell electrodialysis unit which used a slurry of carbon for elution transfer to enhance the movement of ions across a membrane in cell pairs. The following results were demonstrated for a NaCl solution in her laboratory cell stack:

Cf Feed	Cp Product	Output $m^3/m^2/d$	DC Energy $kW\ h/m^3$	Brine Concentration (ppm)	Volts/ Cell Pair
2,500	500	1.81	1.04	86,000	0.7
1,000	430	4.2	0.29	--	0.7
500	10	1.05	0.63	47,000	1.0
485	50	2.36	0.34	--	1.0
1,000	50	1.4	0.2	26,000	1.5
100	10	2.08	0.12	23,000	1.?

The very high brine concentration levels achieved and low energy consumption led to the thought that perhaps this process could be developed into a useful metallurgical concentrating device.

ALBANY INTERNATIONAL

March 24, 1983

Mr. Hans von Michaelis
Randol International Ltd.
7510 West Mississippi #210
Lakewood, CO 80226

Dear Mr. von Michaelis:

It was a pleasure to meet you in Atlanca. As we agreed during our conversation, I am sending to you information on our membranes. Albany Interntional has developed a range of composite reverse osmosis hollow fiber membranes with unique properties. Our membranes can work in extreme pH's, at temperatures and under chemical conditions that no other known membrane system can afford. This seems to provide opportunities for their utilization in hydrometallurgical operations, where pH's can vary from very acidic to very basic, where fluid temperatures may be quite high, and where different oxidizing or reducing agents are present.

We belive that at least the following uses of our membrane in hydrometallurgy would be worth considering.

Concentration of Cations. Preliminary experiments show just in one stage we can easily increase concentrations of copper and nickel in a leaching stream 4-5 times;

Recovery of Ammonia. Our membrane is capable of passing undissociated ammonia while retaining metal ions which allows us to suggest its use in separating ammonia from ammoniacal leachate solutions, and in this manner avoid the high energy consuming recovery of ammonia by distillation;

Treatment of Waste Streams with Recovery of Values. This can become another area of utilization of our membrane. At present we are collaborating wih a major mineral acid manufacturer who has a serious environmental problem with waste ponding. We have demonstrated the feasibility of concentrating a dilute acid waste with our membranes to a level where the value of the concentrate pays for the process. Fresh water for reuse and control of environmental contamination are bonus benefits.

As I have already mentioned to you, we have developed other composite membranes which are able to enrich air to 50% oxygen in one stage quite economically. Oxygen enriching membranes can be useful in both pyrometallurgy and hydrometallurgy.

In summary, I'd like to say that there appears to be a lot of potential for using our membranes in metallurgical processing. We would be happy to run tests on streams of interest to the metal manufacturers at our expense. This can be done by them supplying us with actual samples (about 25 gallons) or by us modeling their composition in our laboratory, based upon information supplied by them.

Enclosed herewith is some literature describing Albany International Company, its Membrane Development Venture and some of the unique features of our membranes. We are looking forward to hearing about the progress of your survey.

Good luck.

Very truly yours,

Alla Kan

PRELIMINARY RESULTS OF AMMONIA RECOVERY REVERSE OSMOSIS PROCESS.

Two types of solutions were tested: The first one was a simulation of waste streams and contained 530 ppm of copper, 167 ppm of nickel and a total 5.4 gr/L of ammonia (both as ammonium ion and free ammonia).

The second solution contained a higher concentration of the ingredients: 9300 ppm of copper, 960 ppm of nickel and a total ammonia concentration of 70 gr/L. Both solutions were treated with calcium hydroxide to precipitate gypsum, which was filtered out before feeding the solution to the RO module at 400 psi.

The unit was operated to take about 80% of the feed volume through the membrane as permeate, thereby causing a four to five-fold concentration of metals in the concentrate, while 60-80% of the ammonia passed into the permeate.

The results of the test are presented in Table 1.

	Test I				Test II			
Metals (ppm)	Cu	Ni	Ca	NH_3	Cu	Ni	Ca	NH_3
Feed	9,280	960	580	58,700	530	167	542	5,070
Concentrate	54,720	5,590	2,780	36,400	1,970	634	2,060	7,610
Permeate	250	38	8	64,100	20	4	16.2	4,140
Rejection %	97.3	96.1	98.7	-9.4	96.3	97.3	97.0	18.3

To prevent calcium sulfate precipitation from the concentrate, a specific anti-precipitating agent was injected into the influent feed, which postponed crystallization for more than 1.5 hours and significantly decreased the possibility of membrane fouling with calcium sulfate.

These results allow us to suggest the incorporation of reverse osmosis into the hydrometallurgical process (figure 1). Probably there are several other points for introducing which could be discussed and tested later.

ECONOMICAL ESTIMATION OF SUBSTITUTION OF AMMONIA DISTILLATION FOR RO AMMONIA RECOVERY PROCESS.

A preliminary economic evaluation of the introduction of RO into the hydrometallurgical technology has been done to compare capital, operating, and energy expenditures for RO and adsorptive removal of ammonia from the flows.

Three categories of expenditures to consider in calculating the impact of RO on the cost of an overall process are: capital costs, which include the costs of the equipment, installation costs of this equipment and operating costs, which include labor, utilities, maintenance, insurance, taxes, etc.

Complete data specifying the current costs of hydrometallurgical equipment, its installation and operation are not readily available. However, reasonable approximations can be made by the following approach:

1. Most of the capital and operating costs obtained from manufacturers, catalogs of equipment, or reported in the literature were updated to 1982 using the Consumer Price Index as reported in "Monthly Labor Review", "Chemical Marketing Report", or "Survey of Current Business".

The operating economical parameters are presented in the table.

OPERATING ECONOMICAL PARAMETERS

Name	Unit	Parameter
Electricity	kWh	$ 0.065
Steam	10^6BTU	$ 4.1
Maintenance	% of Capital Costs	5%
Administration insurance, taxes	% of Capital Costs	7%
Labor	Hour	$12.5
Interest Rate	%	12%

2. Capital and operating costs were calculated per industrial unit with inlet flow of the leachate 30 gal/min. This unit works 350 days a year, 24 hours a day processing 15.1 x 10^6 gallons of leachate per year. Installation costs were assumed 25 percent of the capital costs. Depreciation time was assumed to be 10 years.

3. Electricity consumed by the conventional unit (figure 2), is derived from:

40 HP x 24 hr. x 350 days x 0.746 kW/HP = 251,000 kWh

The cost of electricity is:

251,000 kWh x 0.065 $/kWh = $16,600/year.

4. Cost of steam needed for ammonia evaporation was assumed $4.10/$10^6$ BTU, based on the cost of fuel oil and data obtained from the report, "Technical and Economical Feasibility of Membrane Technology", by Andrew M. Sandre of American Crystal Sugar Company, Moorhead, Minnesota.

The inherent heat of evaporation of ammonia from water is 34 kJ/mol or 32.2 BTU/mol. (Handbook of Analytical Chemistry, by Louis Meites, NY, 1963). Ammonia concentration in the leaching solution was assumed 227.1 gr/gal. Molecular weight of ammonia is17, therefore every gallon contains 13.3 moles ammonia, from which 80% or 10.6 moles are to be recovered. The energy consumed for that operation is 32.3 BTU/mol x 10.6 mol/gal = 341 BTU/gal of leaching solution.

The cost of steam consumption for ammonia evaporation was calculated:

$$341 \text{ BTU/gal} \times 15.1 \times 10^6 \text{ gal/year} \times \frac{\$4.10}{10^6 \text{BTU}} = \$21,110/\text{year}.$$

5. It is supposed that one worker can operate ten units during one 8-hour shift. The labor cost is assumed:

350 days/year x 24 hr/day x 12.5 $/hr. = 105,000 dollars per 10 units per year.

Per one unit the labor cost will be $10,500 per year.

The following tables represent the estimated costs of processing of 1,000 gallons of ammoniacal solution with the conventional method.

Capital and Installation
Costs of Conventional Hydrometallurgical
Ammonia Recovery Process

Cost Items	Units	Cost, $1982 per year
Capital Costs:		
LTV-evaporator	1	48,000
Packed Adsorption Tower	1	125,000
Centrifugated Filter-Mixer	1	18,000
Pump	3	3 x 4200 = 12,600
Auxiliary Equipment	1	4,000
Total Capital Costs		207,600
Installation Costs		51,900
Total Capital and Installation Costs		259,500

Operating Costs of Conventional
Hydrometallurgical Ammonia Recovery Process

Cost Items	Cost, $1982 per year
Operating Costs:	
Depreciation	25,950
Maintenance	11,000
Administration, insurance, taxes	15,400
Labor	10,500
Utilities:	
Electricity	16,600
Steam	21,110
Total Operating Costs	100,560

Assuming that one unit is processing 15.1×10^3 thousand gallons per year the processing cost for 1000 gallons of solution:

$100,560/year:15, 100 thousand gallons/year = 6.66 dollars per 1000 gallons of the ammoniacal solution.

5. Electricity consumed by the RO unit (figure 3) is derived from:

35HP x 24 hr. x 350 day x 0.746 kW/HP = 220,000 kWh.

The cost of electricity is:

220,000 kWh x $0.065/kWh = $14,300/year.

7. Cost of steam needed for ammonia evaporation from 8,640 gal/day of RO concentrate (instead of 43,200 gal/day of the initial solution):

$$341 \text{ BTU/gal} \times 3.02 \times 10^6 \text{ gal/year} \times \frac{\$4.10}{10^6 \text{BTU}} = \$4,220/\text{year}.$$

8. The labor cost assumed the same as the previous case, $10,500 per year.

9. Costs of Membrane Modules - Experimental results presented here were obtained on the preproduction size modules with the membrane area 30 sq. feet. As we estimated the commercial size modules would have 500-2000 sq.ft. membrane area with productivity 2-2.5 gal/sq.ft./day.

Our estimations show that the cost of the membrane system will be $1.60 per gallon per day during a year.

Therefore, the cost of membranes for the unit chosen for this estimation is:

43,200 gal/day x $1.6/gal = $69,120/unit.

The tables on the following page represent the estimated costs of processing 1,000 gallons of ammoniacal solutions with the RO process incorporated.

Capital and Installation Costs
of RO Ammonia Recovery Process

Cost Items	Units	Costs, $1982 per year
Capital Costs		
LTV evaporator*	1	14,000
Packed Adsorption Tower*	1	30,000
Centrifugated Filter-Mixer	1	18,000
Pump (5 HP)		4,200
Pump (4 HP)		3,600
Pump (1 HP)		1,000
RO Pump (8 HP)		6,000
Membrane Modules		69,120
Total Capital Costs		145,920
Installation Costs		36,480
TOTAL CAPITAL AND INSTALLATION COSTS		$182,400

*One can use evaporation - adsorption equipment, installed at the plant, not utilized in the full capacity or combine several batches.

Operating Costs of RO Ammonia Recovery Process

Cost Items	Costs, $1982 per year
Operating Costs	
Depreciation	18,240
Maintenance	7,660
Membrane replacement (assuming membrane life 2 years)	23,600
Administration, insurance, taxes	10,750
Labor	10,500
Utilities	
Electricity	14,300
Steam	4,220
Total Operating Costs	$89,270

Assuming that one unit processes 15.1 x 10^3 thousand gallons per year, the processing cost for 1000 gallons of solution is:

74,550:15, 100 thousand gallons/year = 5.91 dollars per 1000 gallons of the ammoniacal solutions which gives savings of .75 cents/1000 gallons.

Assuming nickel concentration in the solution of 10 gr/L or 83.7 pounds/1000 gallons, and yearly nickel production of 10,000 tonnes, the total savings introduction of RO only for the recovery of ammonia from the leachate can bring

$$\frac{10{,}000{,}000 \text{ kg/year } 0.75 \text{ dollar/1000 gal}}{0.452 \text{ kg/lb. x } 83.7 \text{ lb/1000 gal}} = \$198{,}200/\text{year.}$$

AMD Disposal: A Systems Approach 1225

INTRODUCTION

Acid mine drainage (AMD) is the most serious environmental problem of the mining and mineral processing industry. It causes the discharge of toxic contaminants from mines and mineral waste that continues for many centuries after a mine, mill, or colliery has shut down. Acid mine drainage inhibition would get to the root of so many environmental impact problems that there is no more urgent need for further research and development than this.

Acid mine drainage (AMD) refers to water draining or pumped from mines or draining through or from wasterock piles, overburden and tailings, or which has come into contact with sulfide minerals in any possible way that may have affected its quality, usually by a drop in pH and/or an increase in TDS, especially sulfates, iron, and often a variety of base and heavy metals. Frank Carruchio of the West Virginia Acid Mine Drainage Technical Advisory Committee has observed that only one type of pyrite, the framboidal variety, generates AMD along with other more reactive iron sulfide minerals such as pyrrhotite and marcasite. Whether or not this is so in all environments remains to be established.

In some parts of West Virginia, the need to inhibit AMD from spoil in order to operate a coal mine is preventing coal from being mined because no economic way of preventing it has been found.

Not all mine drainage and effluents from tailings are acid. Even neutral or slightly alkaline waters can contain contaminants that require removal, but these problems are often small compared to the more prevalent acid mine drainage.

Acid mine drainage impact on water quality ranges from small scale problems from small coal mines and even small clay pits to the more significant problems associated with the mining of massive sulfide orebodies and large scale mining of Precambrian conglomerate ores, for example, the uranium mines around Elliot Lake in the Canadian Shield and the gold and uranium mining industry in South Africa, each generating huge quantities of wasterock and tailings. The greatest source of AMD is the coal mining industry with the large quantities of sulfide-bearing waste, particularly in Appalachia, but occurring just about everywhere that coal is mined. Massive sulfide base metal mine and mill waste is almost always a potential source of acid mine drainage. What these all have in common is the presence of sulfide minerals in the ore, wasterock, and tailings material.

AMD has been known to be associated with coal mining for many years, but only within the last decade or so has its full extent in the rest of the mining industry started to be appreciated. Recognition of acid mine drainage from base metal mining still is only partially acknowledged, and in the gold and silver mining industry of the Witwatersrand, it has been identified as a phenomenon to be dealt with in water pumped from some of the deep underground mines. The possibility of larger diffuse source impact of AMD from mine wasterock piles and mine tailings dams has yet to be determined. It is likely that

these will become important targets for remedial programs within the next five years. That Witwatersrand gold and uranium mines tailings and wasterock are acid generators is obvious when these sites are inspected from the air. The table from SMITH, et al. (1984) inserted below indicates that although there is evidence of AMD in groundwater below Witwatersrand tailings impoundments, the problem may be partly alleviated by the way tailings are disposed of in that industry center. Note pH, Mn, and SO_4 levels.

OBJECTIVES OF AMD INHIBITION

Acid mine drainage from sulfide-containing tailings and wasterock piles as well as from old mineworkings can continue for centuries, and AMD treatment would be required to meet effluent discharge regulations; this has resulted in the need to maintain and operate treatment plants "in perpetuity." Consequently, the goal of AMD inhibition must be to avoid such needs for perpetual maintenance of tailings and wasterock disposal sites and, above all, to avoid the need for "perpetual" water treatment.

COMPARISON OF TOTAL CYANIDE LEVELS WITH GROUNDWATER COMPOSITION

DESCRIPTION OF DAM	TOTAL CN	TDS	SO_4	Fe	Mn	PH
① OPERATIONAL DAM ± 5 YEARS AGE	<0.01	712	317	0.1	15	6.8

SECOND INTERNATIONAL CONGRESS OF THE INTERNATIONAL MINE WATER ASSOCIATION (IMWA)

GRANADA, SPAIN
17 to 21 September, 1985

Hopefully the day will come when large pyrite and other iron sulfide and AMD resources are sought after as profitable resources of sulfur and hydrogen; additional resource recovery will then provide a profitable solution to what today are some of the most serious potential environmental liabilities of mining.

TEN ASPECTS OF ACID MINE DRAINAGE INHIBITION

Ten aspects of acid mine drainage (AMD) abatement were encountered during the course of the RANDOL study:

1) Climate.

2) Encouraging laboratory scale demonstration of AMD inhibition through special techniques in revegetation of tailings by CANMET, Ottawa.

3) The U.S. Bureau of Mines work by Robert L. P. Kleinmann, et al. in the use of anionic detergents.

4) Brand new research by Dr. Al Stiller at the University of West Virginia in the application of low grade phosphate rock.

5) Successful control of AMD in restoration of the active coal mine waste dump at Burnside Colliery, Natal, South Africa.

6) Experience at the Kromdraai Coal Mine restoration site, Transvaal, South Africa.

7) Results reported by BOSMAN (1982) and WATSON (1982) on removal of water from underground mines.

8) AMD abatement by discouraging bacterial action.

9) Wasterock utilization.

10) Concentrate stockpiles and transportation.

11) Backfill of Tailings and wasterock.

1. Climate

Climate has a major impact on AMD generation and possible ways of inhibiting it.

Dry Climates: In dry climates with net evaporation, as long as AMD can be contained, it will evaporate. For tailings and wasterock piles that contain sulfides, this implies that provided groundwater is protected from seepage where necessary and runoff is collected and impounded, the problem of AMD would be containable.

Volumes of AMD pumped from underground mines on the Witwatersrand, on the other hand, are so large that evaporation would require enormous land areas and, besides, this would be a waste of water in an area that is short of water.

Revegetation as a means of stabilizing tailings is more difficult in very dry climates. Revegetation of large tailings areas would possibly require more water than can be spared. In drier climates, vegetation may not be lush enough to generate an adequate oxygen barrier to inhibit oxidation of sulfides in tailings. Revegetation of tailings on the Witwatersrand has made a major difference in the control of dust which used to be a major problem in Johannesburg. Non-vegetative ways of stabilizing tailings surfaces have also been demonstrated, but these will do little to prevent AMD generation in the tailings. A dry climate makes the use of "semi-dry" or "sub-aerial" tailings deposition more effective. This method of applying tailings in thin layers which are decanted and allowed to dry between applications and can, depending on the nature of the material, result in extremely impermeable tailings that may effectively encapsulate acid generators in some cases. This method of tailings disposal lends itself to further examination to determine whether it can perhaps be further developed with AMD inhibition in mind.

Wet Climates: In wet climates with a net precipitation, runoff and collected seepage water cannot simply be contained in a pond as the volume of water in the impoundment will eventually exceed the size of the pond because of precipitation. In the end, a discharge will be unavoidable.

Revegetation in a wet climate is easier and can be much more prolific. The rate of humus development in a wet climate with prolific seasonal growth of deciduous plants is faster, and there is a hope of generating a surface oxygen barrier of decaying organic matter on the surface.

Rate of evaporation can be enhanced through vegetation due to evapotranspiration of plants which have a large surface area.

To date, most mining company efforts to revegetate tailings have focused on determining how much lime to add and what seeds will grow. There has been considerable success in some cases. However, the focus has been on getting plants to grow in a way that controls dust and hoping that AMD will be inhibited. Understanding of the mechanisms and fundamental aspects of acid mine drainage generation and how to prevent it are largely not understood as yet.

Much more testwork on the effects of revegetation of various kinds on AMD generation is required, particularly under field conditions.

2. Encouraging Lab Scale Demonstration Through Special Revegetation Techniques

CANMET has undertaken several series of laboratory-simulated tailings disposal. They are able to simulate many years of the life of a tailings impoundment in a much shorter space of time for study purposes in "Lysimeter" tests. A three-year test simulating a 25-year period on uranium tailings was described by RITCEY and SILVER (1982), whose paper is inserted in Chapter 58 on Tailings Impoundments.

In one series of lysimeter tests, four different revegetation approaches have been simulated side-by-side over sulfide tailings. Seepage through each has been collected and monitored for AMD, and markedly different results obtained. In all but one case, the seepage was acid, indicative that normal revegetation does not inhibit AMD. Special measures were taken in the lysimeter in which AMD inhibition is demonstrated and, even there, AMD inhibition is not perfect. These lysimeter tests are still ongoing at CANMET and can be inspected in Ottawa.

The comparative lysimeter tests by CANMET are one aspect of their study which have made a good start in first understanding what processes, influencing factors, and end results are involved in disposal of sulfide-bearing tailings. Certainly, they have shown that the various ways in which tailings can be disposed have a major impact on the composition of seepage and runoff and that this problem is much more complicated than is generally realized.

The CANMET studies to date have accumulated more basic data and information than has been gathered on AMD from tailings as well as experimental procedures of immense value than is available anywhere else. This work clearly represents an important and promising beginning in defining fundamental aspects of the problem and in finding useful answers. This crucial program hopefully will receive all the funding it needs to continue in the lab and be extended to field demonstration.

Other useful work in tailings disposal in which several years are simulated in a shorter space of time in the laboratory have demonstrated the "semi-dry" or "sub-aerial" tailings disposal method also for uranium tailings at ONTARIO RESEARCH FOUNDATION and at SHERRITT-GORDON MINES LTD. These, however, looked more at encapsulation and permeability effects rather than at the effects of revegetation methods:

3. Anionic Surfactants

Work on the inhibition of acid mine drainage using anionic surfactants has been adequately described by the following publications: KLEINMANN (1982), KLEINMANN and ERICKSON (1982), KLEINMANN and ERICKSON (1983), and FOX (1983).

The mechanism whereby the bacteria are destroyed after coming in contact with the anionic surfactant is of interest. Bacteria such as thiobacillus ferroxidans which enhance the oxidation of sulfides to acid and ferrous/ferric ions are fragile cells which survive in the acid medium by surrounding themselves with a protective coat of polypeptide material.

The surfactant however causes this protective coat to be rendered imperfect to the extent that they are no longer viable in the acid medium and die as soon as acidity starts to develop.

Efforts to spray anionic surfactants into mineworkings to inhibit acid mine drainage underground seem less promising although work is progressing on the use of a volatile fume that could possibly penetrate cracks or fissures more effectively. Two of the reagents being tested are potassium benzoate and sodium sorbate.

Spraying anionic surfactants over surface waste dumps on a regular basis to inhibit AMD generation amounts to a perpetual treatment process requirement which, for that reason, is not likely to be the final answer.

The use of anionic surfactants such as sodium lauryl sulfate mixed into elastomer as slow release agents scattered over the waste dump that has been contoured and restored before adding a layer of topsoil and establishing plant growth is being evaluated. It is hoped that by the time the slow release agent has dispensed all the anionic surfactant, that the soil and organic material from the vegetation will have built up to keep oxygen from reaching the pyritic materials. Work by the Chamber of Mines in South Africa has shown that oxidation of pyrite in gold mine dumps was not prevented by the establishment of grass vegetation on the dumps. However, considering the very different climatic and vegetation conditions that prevail in most of the eastern and central U.S.A. coalfields, it is possible that the result may be different. First, North American winters are so cold as to inhibit AMD generation. Second, because summers are so hot and humid, deciduous growth is prolific and would generate much more organic matter in the soil than on the Witwatersrand. Many U.S. coal mines are currently testing acid mine drainage inhibition following the techniques of KLEINMANN, et al., and within a few years, it will be possible to determine the degree of success achieved. Meanwhile, the results to date indicate a short-term success but are still inconclusive as to a long term result that would allow operators to walk away from the site without further attention.

Several commercial companies manufacture anionic surfactants for AMD inhibition on a trial basis. Manufacturers of sodium lauryl sulfate are:

Primary Examiner—Dennis L. Albrecht

[57] **ABSTRACT**

Acid drainage from exposed pyritic m[illegible] such as coal mine tailings is reduced through the controlled application of anionic detergents which inhibit the bacterium *Thiobacillus ferrooxidans*. The controlled application of anionic detergent comprises an initial application of anionic detergent in sufficient quantities to satisfy the adsorptive capacity of clay or clay-sized particles overlying the pyritic material coupled with the application of an anionic detergent inhibitor of *Thiobacillus ferrooxidans* from a slow release matrix containing the inhibitor. The two applications are to intercept infiltrating water up-gradient of the pyritic material or strata. The amount of matrix employed is calculated in accordance with a described formula. The method can be used to reduce acidity in drainage from pyritic mine tailings, coal mines, coal refuse piles and construction sites at which acid drainage is a problem.

Acid drainage is also reduced by the mere controlled application of specific anionic detergents which inhibit the bacterium *Thiobacillus ferrooxidans* utilizing a detergent-containing matrix which provides detergent concentrations of greater than 10 ppm and preferably greater than 25 ppm in the infiltrating water.

METHOD OF CONTROL OF ACID DRAINAGE FROM EXPOSED PYRITIC MATERIALS

RELATED APPLICATION

This application is a Continuation-in-Part of my copending application, Ser. No. 94,426, filed Nov. 15, 1979, abandoned on the filing date of this application, all the teachings of which copending application are incorporated herein by specific reference thereto.

BACKGROUND OF THE INVENTION

1. Field of the Invention

This invention relates to a method for the reduction of acidity in drainage from pyritic mine tailings, coal mines, coal refuse piles and construction sites.

2. Description of the Prior Art

Acid drainage results from the oxidation of iron pyrite (FeS_2) associated with coal, mine tailings and overburden material. The problem of acid formation also may occur during building or road construction due to pyrite present in the disturbed strata. The conventional technique to overcome this problem has been to collect the drainage from the area and then neutralize it with lime and/or limestone.

Previous research by biologists suggests that a bacterium, *Thiobacillus ferrooxidans*, plays a role in the acid formation process. However, geologists have remained sceptical of such research primarily because the laboratory experimental conditions tend to deviate radically from actual field conditions. Hence any correlation between laboratory and field conditions is suspect.

The tolerance of *T. ferrooxidans* to a large range of chemical substances has been examined in the literature. Indeed, two detergents, alkyl benzene sulfonate and sodium lauryl sulfate, were tested by Dugan and Lundgren in 1964 and shown to inhibit *T. ferrooxidans* at concentrations of 2–5 ppm in culture media. Another detergent was also tested and found inhibitory at only extremely high concentrations. The inhibition observed was attributed by Dugan and Lundgren to a coating of the bacteria caused by the detergents' alkyl side chain.

It is of course possible to protect coal from contact with water and thereby prevent formation of acid drainage by coating each individual particle with various oils and waxes. Moreover, coal may be protected as disclosed in U.S. Pat. No. 2,204,781, Wattles, by spraying the outside surface of piles or large masses of coal with a material congealable at atmospheric temperatures whereby a non-tacky weather resistant jacket adherent to the coal at the surface of the pile or mass is formed. However, both of the foregoing procedures require substantial expenditures of coating material, and are not practical where the primary purpose is to avoid acid drainage as opposed to the prevention of water contact.

One prior art approach to prevention of acid drainage relates to treatment with an aqueous alkali metal silicate solution which reacts with acid present to form a sila gel which in turn may coat the pyrite surface. (U.S. Pat. No. 3,094,846). Another prior art method of preventing acid drainage involves use of a mixture of pulverized phosphate and sulfuric acid to precipitate soluble iron as phosphates which in turn may coat the pyrite surface. (U.S. Pat. No. 3,443,882).

In accordance with this invention acid drainage in a pyritic material which is exposed to water is controlled by addition of at least about 10 ppm of an anionic detergent capable of inhibiting *T. ferrooxidans* to the water which contacts the exposed material. The concentration is necessarily higher than that previously reported to be required to inhibit *T. ferrooxidans* in culture media. In order to avoid repopulation, the addition is effected by controlled release from a matrix containing anionic detergent dispersed therein. Controlled addition is accomplished by placement of the matrix to intercept infiltrating water upgradient of the pyritic material. The quantity of anionic-detergent containing matrix required to effect the controlled release is calculated in accordance with the formula set forth in the summary of the invention.

I have developed a method of dealing with acid drainage which, unlike the conventional prior art, does not address the problem by treating the resultant acid, but rather prevents acid formation in a facile and economically viable manner.

SUMMARY OF THE INVENTION

This invention relates to reducing acid drainage in a pyritic material which is exposed to water by controlled addition of at least about 10 ppm of an anionic detergent capable of inhibiting *T. ferrooxidans* to the water which contacts the exposed material by controlled release from a matrix containing anionic detergent dispersed therein. The matrix may be an elastomer and may be comprised of rubber. The matrix may alternatively be a high melting point wax. Controlled addition is accomplished by placement of the matrix to intercept infiltrating water up-gradient of the pyritic material.

The pyritic material which may be treated includes pyritic mine tailings, pyritic coal mines, pyritic coal refuse piles and pyritic construction sites; however, any mass of pyritic material susceptible to acid drainage may be treated in accordance with this invention.

The anionic detergent may be selected from the group consisting of *Thiobacillus ferrooxidans*-inhibiting water soluble salts of (a) alkyl aryl sulfonic acids, (b) alkyl sulfonic acids, (c) alkenyl sulfonic acids, (d) sulfonated alkyls, (e) sulfonated alkenyls, (f) sulfated monoglycerides, (g) sulfated fatter esters. Above a pH of about 2.5, sodium lauryl sulfate is preferable.

This invention relates to a method of reducing acid drainage in a pyritic material which is exposed to water, which method comprises adding at least about 10 mg of an anionic detergent which inhibits the bacterium, *Thiobacillus ferrooxidans* per liter of said water which contacts the exposed material.

Pyritic material at construction sites is predominately associated with clays or shales. Pyritic material is also associated with shale tailings obtained after extraction of hydrocarbonaceous material therefrom. Moreover, coal refuse piles contain substantial quantities of clay and shale fragments. Accordingly the overall treatment to reduce acid drainage should preferably be adapted to provide for saturating adsorption sites or these non-pyritic particles associated with pyritic materials during the initial stage of anionic detergent application. Initial application of anionic detergent to saturate adsorptive sites of adsorbtive compositions associated with the pyritic material can be before, at the time of or after placement of the controlled release matrix. Such initial treatment may precede or follow placement of the matrix by a matter of weeks, although substantially longer periods are also suitable.

The most-preferred embodiment of this invention comprises an initial application of anionic detergent to

saturate the adsorptive capacity of clay particles associated with the pyritic material coupled with addition of anionic detergent by controlled release from a matrix containing said anionic detergent dispersed therein. Specifically, the initial application consists of an anionic detergent applied at concentrations greater than 50 mg per liter of water and typically at least 100 mg per liter of water. Controlled release addition of anionic detergent is effected by controlled release from a matrix containing said anionic detergent dispersed therein. Specifically the addition is effected by placing the matrix containing said anionic detergent dispersed therein to intercept infiltrating water up-gradient of the pyritic material.

The quantity of matrix required to effect controlled release which is placed up-gradient of the pyritic material is represented by Q, determined in accordance with the following formula:

$$Q = \frac{Pa\ I\ A\ C}{Dr\ R} \cdot 10$$

Q = the quantity of detergent-continuing matrix in kg

Pa = the numeral representing the annual average precipitation in area [m]

I = percent infiltration

A = the numeral representing the area to be treated in M^2

Dr = the numeral representing the detergent-release rate for matrix at particle size range to be used, mg detergent/kg matrix year

R = the numeral representing the effective release-life of the matrix in years

C = the numeral representing the optimal average concentration of detergent in mg/l

The percent infiltration, I, is site-specific and generally is estimated at 50% for reclaimed or undisturbed land surfaces and 75% for coal refuse and unreclaimed surface mines.

The annual detergent release rate, Dr, is determined by measuring detergent release under saturated conditions. It is expressed as mg detergent/kg matrix year.

The effective release life of the matrix is dependent on the specific matrix and falls within the range of about 2 to about 5 years.

The optimal average concentration of detergent is generally about 20 to about 25 mg/l for sodium lauryl sulfate and about 20 to about 40 mg/l for the other anionic detergents.

Preferably, the anionic detergent is added in an amount of at least about 25 mg per liter of said water. The matrix is preferably in particulate form with shredded particles of a size of about one inch preferred. Anionic detergents suitable for this invention are (a) alkyl aryl sulfonic acids, (b) alkyl sulfonic acids, (c) alkenyl sulfonic acids, (d) sulfonated alkyls, (e) sulfonated alkenyls, (f) sulfated monoglycerides and (g) sulfated fatty esters. Among the foregoing anionic detergents are the long chain alpha olefin sulfonates; soluble salts of alkenyl sulfonic acid such as the sodium salt of C_{14}–C_{16} alpha olefin sulfonates; water soluble alkenyl aryl sulfonic acid salts; water soluble alkyl aryl sulfonic acid salts such as sodium alkylnaphthalene sulfonate and sodium alkyl benzene sulfonate; water soluble salts of sodium lauryl sulfate; and water soluble salts of sulfated monoglyceride.

The matrix may be an elastomer such as rubber or a high melting point wax or other suitable material capable of slow release of the detergent.

DETAILED DESCRIPTION OF THE INVENTION

One aspect of this invention resides in the discovery that high levels of certain anionic detergents having a long alkyl chain of 6 or more carbon atoms, are effective in reducing or stopping acid drainage from water-exposed pyritic materials. Concentrations of at least about 10 ppm and preferably within the range of from about 10 ppm to about 20 ppm have been found to inhibit bacterial activity of *T. ferrooxidans*, and levels above about 20 ppm kill the bacteria.

An important aspect of this invention relates to the initial application of anionic detergent. The primary purpose of this initial application is to reduce subsequent adsorption of anionic detergent by clay particles up-gradient of the pyritic material by saturating absorptive capacity which would otherwise reduce the effectiveness of the controlled release. A secondary purpose is a rapid reduction in population of *Thiobacillus ferrooxidans* in and up-gradient of the pyritic material.

The amount of anionic detergent required for the initial application depends on the volume of pyritic material, the volume of overlying material and the percent clay content of the overlying material. Preferably, the detergent is applied in a concentration of at least 100 mg/l, in sufficient volume so that each acre-foot of pyritic material is treated with the equivalent of 7 pounds of detergent (ie. 85 gallons of 1% solution, or 1,000 gallons of 850 ppm solution). In practice, the initial application can be estimated in one of two ways:

1. by estimating adsorption from the percent clay and silt present in overlying material. Each foot of silt-clay can be assumed to adsorb approximately 10–15% of the initial application. Strata containing lesser amounts of silt and clay can be assumed to adsorb proportionally lower amounts. Thus, for example, if there was six feet of disturbed strata overlying the pyritic material, of which four feet was primarily fine-grained and two feet was a mixture of fine- and coarse-grained material, an initial application would be calculated by multiplying the required concentration in the pyritic material by the mount adsorbed by the overburden, ie. four feet of fine-grained material will adsorb 40–60%, two feet of mixed material will adsorb 10–15%. Thus a minimum application for the given strata would be approximately three times that required to treat the pyritic material. Thus, for a quarter-acre site containing a foot of potentially acid-forming material and the described overburden, an appropriate initial application estimate would be 5 pounds of detergent (7 pounds of detergent × 0.25 acre-feet × 3) or 1,000 gallons of 600 ppm solution.

2. by application of detergent at concentrations of at least 100 ppm until groundwater samples, taken immediately down-gradient at the pyritic material, foam upon gentle agitation. Monitoring stations should be as near as possible to the pyritic material; it is not desirable nor appropriate to apply detergent until streams in the area are foaming.

Another aspect of this invention resides in the discovery that the potential problem associated with the high solubility of anionic detergents and easy re-establishment of bacteria where anionic detergent is not continuously present, can be overcome by the continuous and controlled release of anionic detergent from a matrix.

Where an elastomeric matrix, e.g. a rubber comprising matrix is employed, preferably the ratio by weight of anionic detergent to elastomer is from about 30 to about 80 parts by weight of anionic detergent per hundred parts by weight matrix.

Examples of suitable controlled release compositions are set forth in the table which follows:

FORMULATIONS CONTROLLED RELEASE ANIONIC SURFACTANT (DIFFUSION - DISSOLUTION) I	
natural rubber	50 parts
thermoplastic styrene butadiene	50 parts
carbon black	10 parts
anionic detergent	10–50 parts
II	III

Still another aspect of my invention resides in my discovery that water soluble alkenyl sulfonates such as alpha olefin sulfonates, and specifically long chain alpha olefin sulfonates, suitably C_{14}–C_{16} admixtures are effective as *Thiobacillus ferrooxidans* inhibitors when dispersed within a slow release matrix. Sodium salts of C_{14}–C_{16} alpha olefin sulfonates are particularly preferred.

I have also discovered that water soluble alkylnaphthalene sulfonates such as "Alkanol" XC, a sodium alkylnaphthalene sulfonate produced by the DuPont Company are very effective as *Thiobacillus ferrooxidans* inhibitors when dispersed within a slow release matrix.

In addition to the foregoing I have further discovered that water soluble sulfated monoglycerides operate in the same manner as the foregoing alkenyl sulfonates and alkylnaphthalene sulfonates.

It is important to add that, although certain groups of anionic detergents have been found to be effective in reducing the acidity of pyritic mine tailings, anionic surfactants such as "Zonyl" fluorosurfactants, sulfated alkyl ethers, and sulfated ethoxylated alkyl phenols are ineffective in the environment associated with mining drainage, the water soluble salts previously related have been found to be effective. Among the suitable anionic detergents are alkyl aryl sulfonates, long chain alcohol sulfates, olefin sulfates and sulfonates, sulfated monoglycerides, sulfated ethers, sulfo-succinates and alkane sulfonates.

The configuration of matrix which has been found most suitable for use in connection with the method of this invention is particulate, of a size generally of about one inch±one half inch with shredded material being most preferred. Such particles because of irregular surface best retain the configuration of the matrix mass and offer maximal surface area.

EXAMPLE

This example illustrates the results of laboratory testing of pyritic overburden materials under simulated field conditions developed for the purpose of laboratory testing.

Sodium lauryl sulfate (SLS), the sodium and calcium salts of linear alkylbenzene sulfonate (ABS) and alpha olefin sulfonate (AOS) were tested as inhibitors. Natural and synthetic rubber formulations and the amide ester of monoethanolamine and stearic acid (a high melting point wax) were tested as release agents.

Pyritic Material Tested

For laboratory testing coal and overburden materials, collected from Clarion, Pa. and averaging 5% total sulfur, were crushed and sieved to a size within the range of from 0.2 to 2.0 cm. The particles were rinsed with deionized, distilled water.

T. ferrooxidans Employed

T. ferrooxidans obtained from the American Type Culture Collection (ATCC #13728), was cultured in 9-K medium.

Composition of Simulated Rainfall

Simulated rainfall infiltration consisted of a synthetic ground water formulation of water containing 50 ppm $CaCO_3$; 25 ppm $MgSO_4$; 2 ppm $(NH_4)_2$ and 0.25 ppm KH_2PO_4.

Apparatus and Procedure

Tubulated desiccators were used to simulate the humid environment of the intermediate belt of the zone of aeration. The experiments were performed in perforated polypropylene beakers, each containing 50 g rinsed crushed sample material. The beakers were positioned so as to drain into slightly larger beakers and the entire double beaker assemblage was autoclaved before being placed on a tray inside the desiccator. Water beneath the tray was heated for about 15 minutes to provide a humid atmosphere. Two 0.5 cm diameter tubes were inserted through the desiccator lid to allow controlled contact with the atmosphere and to simulate rainfall infiltration. To simulate the presence of *T. ferrooxidans* in natural mine infiltration, a 0.1 ml inoculum of the 9-K medium was trickled onto the samples every three days. Immediately following this, 6.0 ml of synthetic groundwater, with varying concentrations of detergent, was applied. Sterile controls received no inoculum.

At the end of each run, the contents of the beakers were filtered and rinsed with 100 ml deionized, distilled water. Approximately 0.5 g of the test material was placed in 9-K culture medium to test for *T. ferrooxidans*. Oxidation of the medium in 3–4 days showed that the bacterium was present and uninhibited. Oxidation which occurred after 6–10 days was interpreted as lowered population density, due to either partial inhibition or bacteriostatic action.

The collected filtrate was analyzed for total dissolved iron by atomic absorption spectrophotometry, and for acidity, by the hot peroxide method (Standard Methods, No. 402 of "Standard Methods for the Examination of Water and Wastewater", 14th ed., A.P.H.A. Washington, D.C. 1976.)

Inhibitory Effects of Anionic Detergents

Referring to FIG. 1, the effect of sodium lauryl sulfate (LSL); linear alkyl benzenesulfonate (ABS), from Witco C-18, 90% active content; linear alkenyl benzene sulfonate (ABS) from Pilot, C_{14}, also 90% active content, and alpha olefin sulfonate (AOS) C_{14}–C_{16}, 88% active content, in reducing acidity and iron concentrations in water contacting pyritic coal particles containing 5% sulfur is shown.

The inhibitory effect was especially marked for sodium lauryl sulfate, which was also the most effective in limiting bacterial population. Samples containing SLS at concentrations increasing from 5 to 20 ppm showed proportionally delayed growth when transferred to 9-K

culture medium. At 25 ppm, SLS was bactericidal, reducing acidity and iron concentrations to about that of sterile controls. The other anionic detergents as will be noted by reference to FIG. 1 required somewhat higher concentrations to obtain the same effects.

The concentration of detergent necessary to inhibit *T. ferrooxidans* in the simulated mine environment was determined to be greater than that required in 9-K culture media. It is possible that the substrate material reduces the vulnerability of the bacteria, that the detergent does not saturate all of the crushed material before draining or that the effectiveness of detergents in synthetic groundwater differs from that in 9-K medium.

Inhibitory Effect of Controlled Release of Anionic Detergents in Simulated Field Conditions

Controlled release was investigated in laboratory simulated field conditions as a means of administering anionic detergents with each rainfall over prolonged period to a pyritic coal pile wherein the coal contained 5% sulfur. The rubber-detergent formulations were prepared in a Brabender plasticorder by premixing the non-curing ingredients and adding them with the rubber, followed by the curing ingredients after a minute and a half. The wax matrices were prepared by mixing the detergent into the melted wax with a magnetic stirrer and hot plate. All release materials were rinsed before testing.

The rate of release from 5.0 g each of the below-described wax and rubber formulations was ascertained by measuring detergent concentration when the material was rinsed each week, and alternatively, when it was continuously submerged in distilled, deionized water, adjusted to pH 4.5, and in some cases pH 2.5, with H_2SO_4. Also examined was the effect of particle size on detergent release, using duplicate runs of sieved size fractions of 0.42–4 mm, 4–8 mm and 8–40 mm. In all cases, detergent concentration was determined by the methylene blue method. "Standard Methods for the Examination of Water and Wastewater", 14th ed., A.P.H.A., Washington, D.C. 1976.

The results of anionic detergent release from wax and rubber matrices is indicated below in Tables 1 and 2 respectively.

As will be noted by reference to Table 1, release of the detergents from the wax formulations was initially fast, but decreased rapidly with time. However, formulations containing 33% detergent showed a second rapid-release period after about two months as porosity caused by detergent dissolution led eventually to complete disaggregation. Accordingly, high molecular weight formulations which are formulated for long term utilization should comprise at least about ⅓ anionic detergent.

The diffusion-dissolution of detergent from rubber matrix proceeds at a release rate proportional to the square root of time, until approximately 60% of the active agent has been released, after which the release rate drops off exponentially. Thus, the ideal release rate for a rubber matrix would be one in which 60% depletion coincides approximately with the stability lifespan of the matrix.

The daily average release rate for the vulcanized natural rubber formulations set forth in Table 2 would require in excess of twelve years for 60% release of anionic agent release before breakdown of the rubber.

Assuming as the lifespan of the rubber 2–5 years, in order to obtain an ideal coincidence of depletion and matrix lifespan, the mixture of 50 parts natural rubber to 50 parts thermoplastic styrene butadiene rubber, which can be handled without vulcanization, best approximated the ideal formulation. An average release rate of 50 mg/day per g of matrix was observed in the foregoing formulations.

Inhibitory Effect of Controlled Release of Anionic Detergent Under Field Conditions

The detergent-matrix combination which optimized rate of release and inhibition of *T. ferrooxidans* compris-

ing a matrix of an unvulcanized admixture of SBR and rubber was applied to one of two 25 ton coal refuse piles in central Pennsylvania made available by Barnes and Tucker Coal Co. Each pile sat on a plastic sheet and was graded so as to drain in one direction. A perforated pipe ran through each pile and drained into a collecting bucket, which was emptied after sampling. Seven slabs of unvulcanized admixture, each approximately 0.3 m^2 in areas and totalling 27 kg (of which about 27% was an anionic detergent, sodium lauryl sulfate), were placed beneath the surface of one of the piles in such a manner as to minimize interference with natural infiltration. Samples of the drainage from each pile were analyzed for acidity, total dissolved iron, ferrous iron, detergent concentration and population of *T. ferrooxidans* by most probable number ("Standard Methods for the Examination of Water and Wastewater", 14th ed., A.P.H.A., Washington, D.C. 1976.)

The amount of anionic detergent containing matrix necessary for the coal refuse pile was determined from the average laboratory release rate, the horizontal area of the pile (16 m^2) and the average annual rainfall for the area (approximately 100 cm), as heretofor more fully explained. The actual concentration of dissolved detergent dependant on the time interval between rainstorms and the quantity of rainfall and is, therefore, not precisely calculable. It is generally necessary that detergent concentration exceed 10 ppm, preferably 15 ppm and occasionally 25 ppm to prevent bacterial repopulation; therefore, it is preferable to exceed rather than fail to reach the minimal detergent concentration required.

After about 100 days acidity and iron values for the treated pile were less than 1/80 times those observed in the drainage from the control pile. However, detergent concentration was lower than anticipated (approximately 10 ppm) due to the low surface area of the rubber, causing a second rise in acidity, which eventually resulted in acidity ½ the level of the control pile.

The same detergent-rubber combination was field tested on acid-producing overburden material using a pair of leaching tubs at a site in northern West Virginia. The tubs were buried to ground level in pyritic shale and enclosed approximately 0.3 m^2 of the material. One tub was treated with approximately 1.5 kg of the unvulcanized SLS-rubber in pieces approximately 30 cm^2 in area; the other was left untreated as a control. Drainage was collected via tubing leading from the bottom of each, and was analyzed for acidity, total dissolved iron, ferrous iron, detergent concentration and presence or absence of *T. ferrooxidans*.

The West Virginia field test tested the effect of controlled release of anionic detergent on acid production in an abandoned surface mine. Abandoned coal mines produce over three-fourths of the acid drainage of Appalachia. Sufficient rubber was applied to generate an anticipated detergent concentration of at least 25 ppm, assuming a release rate under acid conditions of 20 mg/day per g of matrix. Two weeks after application of the rubber, approximately 250 milliliters of 30% detergent solution was mixed with 1,000 milliliters of water and added to the section treated with the detergent releasing rubber matrix. This application was adopted to saturate the adsorptive sites which were present in the oberburden clays associated with the residual pyritic materials of the abandoned surface mine area where the rubber matrix was applied. The rubber was added to the more acid-producing section and generated a detergent concentration which ranged from 10 to 60 ppm in the drainage (the latter after the winter freeze). *T. ferrooxidans* was observed in the drainage from the untreated control throughout the duration of the experiment. However, it was only present in drainage for three weeks after treatment with the controlled release material and the aqueous diluted detergent solution.

Acidity before treatment averaged approximately 30,000 mg/l (as $CaCO_3$) with a pH of 2.1. Two months after treatment, significant decrease in acidity was observed with 95% reduction after six months. Nine months after treatment, pH of the drainage from the treated section was 6.86 with only 25 mg/l acidity as compared to pH in the control section of 2.0 and acidity of 28,250 mg/l.

It should be pointed out that the effect of particle size on the rate of detergent release has been discovered to be a viable method of obtaining optimal release rate. Table 2 includes release rates for unvulcanized rubber of various size ranges, the finest-grained of which was a coarse powder (between sieve sizes 5 and 40) that gave an average release of 185 mg/day per g of rubber. This would give an expected release life of 2.5 years before 60% depletion, which is a reasonable estimate of the stable lifespan of the buried rubber. At this rate, again assuming an average annual rainfall of 100 cm and a desired detergent concentration of 25 ppm, 37 kilograms would treat a hectare of coal refuse at a cost of $50–75 ($20–30/acre) per year.

It will be obvious that modifications to this process may be made and it is intended to cover such modifications and changes as would occur to one skilled in the art, as the following claims permit and consistent with the prior art.

What I claim is:

1. A method of reducing acid drainage in a pyritic material which is exposed to water, which method comprises:

(1) treating each acre-foot of pyritic material with at least seven pounds of a first anionic detergent which inhibits the bacterium *Thiobacillus ferrooxidans*; and

(2) adding at least 10 mg of a second anionic detergent which inhibits the bacterium *Thiobacillus ferrooxidans* per liter of said water which contacts the exposed material, said addition being effected by controlled release from a matrix containing said second anionic detergent dispersed therein; said first and second anionic detergent being selected from the group consisting of *Thiobacillus ferrooxidans*-inhibiting water soluble salts of (a) alkyl aryl sulfonic acids, (b) alkyl sulfonic acids, (c) alkenyl sulfonic acids, (d) sulfated fatty esters.

2. The method of claim 1 wherein the first and second anionic agents are the same.

3. The method of claim 1 wherein said addition is effected by placing the matrix containing said second anionic detergent dispersed therein to intercept infiltrating water up-gradient of the pyritic material.

4. The method of claim 3 wherein the quantity of matrix placed up-gradient of the pyritic material is represented by Q, determined in accordance with the following formula:

$$Q = \frac{P_s I_a C}{D_r R} \times 10$$

Where:

A = the quantity of detergent-continuing matrix in kg

Pa = the numeral representing the annual average precipitation in area in m

I = percent infiltration

A = the numeral representing the area to be treated in m^2

Dr = the numeral representing the detergent-release rate for matrix at particle size range to be used, mg detergent/kg matrix year

R = the numeral representing the effective release-life of the matrix in years

C = the numeral representing the optimal average concentration of detergent in mg/l.

5. The method of claims 1 or 3 wherein the anionic detergent is added in an amount of at least about 25 mg per liter of said water.

6. The method of claim 4 wherein said matrix is in particulate form.

7. The method of claim 6 wherein said particles are shredded particles.

8. The method of claim 4 wherein the anionic detergent is a long chain alpha olefin sulfonate.

9. The method of claim 4 wherein the water-soluble salt of alkenyl sulfonic acid is a sodium salt of C_{14}-C_{16} alpha olefin sulfonates.

10. The method of claim 4 wherein the anionic detergent is a water soluble alkyl aryl sulfonic acid salt.

11. The method of claim 4 wherein the water soluble alkyl aryl sulfonic acid salt is a sodium alkylnaphthalene sulfonate.

12. The method of claim 4 wherein the water soluble alkyl aryl sulfonic acid is sodium alkyl benzene sulfonate.

13. The method of claims 4 wherein the water soluble salt is sodium lauryl sulfate.

14. The method of claim 4 wherein the water soluble salt is a sulfated monoglyceride.

15. The method of claims 1, 3 or 4 wherein the matrix is an elastomer.

16. The method of claim 15 wherein the elastomer comprises rubber.

17. The method of claim 16 wherein the matrix is a high melting point wax.

Full-Scale Field Trials of a Bactericidal Treatment to Control Acid Mine Drainage

by

Robert L. P. Kleinmann, Supervisory Geologist
Patricia M. Erickson, Chemist

U.S. Department of the Interior, Bureau of Mines
Pittsburgh Research Center
Pittsburgh, Pennsylvania 15236

Abstract. Sodium lauryl sulfate (SLS) is one of several anionic detergents known to be effective in inhibiting the iron-oxidizing bacterium, Thiobacillus ferrooxidans. Since T. ferrooxidans plays a critical role in determining the rate of pyrite oxidation, the Bureau of Mines has investigated the use of SLS as a method to control the formation of acid mine drainage. In previously reported pilot-scale tests, the detergent successfully controlled T. ferrooxidans and thereby reduced acid production 60-90 pct. During the past year, the Bureau of Mines has conducted five full-scale field trials at active and abandoned surface mines and coal refuse piles.

The first of these field tests was at a ten acre inactive refuse pile near Beckley, West Virginia. After a three month lag period, average acidity decreased from 900 mg/l to 350 mg/l and iron decreased from over 100 mg/l to 2 mg/l. An eight acre active section of a large refuse pile was treated similarly; acidity and sulfate decreased from over 4,000 mg/l to less than 100 mg/l and iron decreased from 1,000 mg/l to 2 mg/l or less. At both sites, a single application was effective for about 4 months.

Our other field tests have been at active and abandoned surface mines in Ohio and West Virginia. At two of the sites, SLS was applied both as a solution and in slow release rubber pellets; the latter are an attempt to provide long term control of acid drainage from inactive sites where periodic reapplication would not be feasible.

Introduction

The exposure and subsequent oxidation of sulfide minerals, causes the acidic drainage associated with many coal mines and refuse piles. To meet state and federal discharge regulations, mining companies spend millions of dollars annually to treat acid water. The Bureau of Mines has investigated possible methods of reducing these costs by controlling the rate of oxidation of pyrite, thereby eliminating the acid at its source.

The kinetics of acid formation are dependent on the availability of oxygen, the surface area of pyrite exposed, the activity of iron-oxidizing bacteria and the chemical characteristics of the influent water. Thiobacillus ferrooxidans is the principal iron-oxidizing bacterium involved in determining the rate of pyrite oxidation[1-2]. Acidification progresses in a three-stage sequence dependent upon the activity of T. ferrooxidans and solution Eh and pH[3]. One potential method of slowing pyrite oxidation is by inhibition of T. ferrooxidans. Certain anionic surfactants (cleansing detergents) can be used to kill T. ferrooxidans at low pH in an economical and environmentally safe manner, thus reducing acid formation[4-6].

Background Information

T. ferrooxidans actually accelerates pyrite oxidation by two mechanisms: by direct oxidation and by oxidizing Fe^{2+} to Fe^{3+}, which in turn oxidizes the sulfide minerals[5-10]. Direct oxidation is probably most important during initial acidification, when hydrolysis of Fe^{3+} is too rapid to allow significant ferric oxidation of pyrite.

During the initial stage of this process, fine-grained pyrite is oxidized either by T. ferrooxidans or by air with equal amounts of acidity produced by the oxidation of sulfide to sulfate (reaction 1) and by the oxidation and hydrolysis of Fe^{2+} (reaction 2). The ability of T. ferrooxidans to accelerate the rate of pH decline is important, for each rainfall potentially interferes with the initial buildup of acid. During this stage, it is possible to forestall acidification by adding alkalinity to the reaction system[3]; if alkalinity exceeds acidity, the only major downstream effect is an increase in sulfate concentration. Thus, the addition of lime, soda ash or other sources of alkalinity to freshly exposed pyritic material can stop or postpone acidification. Once acidity significantly exceeds alkalinity, it

becomes much more difficult to return the acid-producing system to stage 1.

$$FeS_2 + \frac{7}{2} O_2 + H_2O \longrightarrow Fe^{2+} + 2SO_4^{2-} + 2H^+ \quad (1)$$

$$Fe^{2+} + \frac{5}{2} H_2O + \frac{1}{4} O_2 \longrightarrow Fe(OH)_3(s) + 2H^+ \quad (2)$$

$$Fe^{2+} + \frac{1}{4} O_2 + H^+ \longrightarrow Fe^{3+} + \frac{1}{2} H_2O \quad (3)$$

$$FeS_2 + 14Fe^{3+} + 8H_2O \longrightarrow 15Fe^{3+} + 2SO_4^{2-} + 16H^+ \quad (4)$$

As decreasing pH causes abiotic oxidation of Fe^{2+} to proceed slowly, T. ferrooxidans takes on its primary role of oxidizing Fe^{2+}, thereby allowing reaction 2 to continue producing acidity and ferric hydroxide. This initiates the second stage of the reaction process. Once again it is possible for the pH to stabilize in this stage, though this will usually occur only when permeability of the spoil is low or the amount of exposed pyrite surface area is small. Otherwise, the pH decline continues to the third stage, where acid is produced in a biologically mediated cycle of reactions 3 and 4[3].

As acidification proceeds and the pH in the immediate vicinity of the pyrite falls to less than 3, the increased solubility of iron results in increased Fe^{3+} activity[11]. At an interstitial pH of approximately 2.5 (corresponding to a drainage pH of 3.5 to 4.0), bacterial oxidation of Fe^{2+} and reduction of Fe^{3+} by the pyrite (reactions 3 and 4) combine to cause an exponential increase in acidity and iron concentrations, as can be seen in figure 1. Eliminating the bacteria halts this third stage and thus reduces acid production by at least 75 pct[3].

The biological literature contains numerous laboratory inhibition studies of T. ferrooxidans conducted in an attempt to understand the unusual

Figure 1. Acidity and total dissolved iron vs. pH for a series of experiments conducted in laboratory simulations of a coal refuse pile.

biochemistry of its metabolism. These demonstrated the vulnerability of T. ferrooxidans to certain metals, organic acids and anionic surfactants[4, 12-15]. After eliminating substances that were environmentally unsafe or too expensive for large-scale use, we decided to test anionic surfactants.

Although T. ferrooxidans lives in acid water, its internal pH is approximately neutral. The anionic surfactants alter the semipermeable properties of the cytoplasmic membrane, allowing seepage of the acid water into the cell[16-24]. These surfactants, used as cleansers in laundry detergent and shampoos, kill T. ferrooxidans in culture medium at concentrations as low as 2-5 mg/l, and in coal refuse at concentrations of 25-50 mg/l[4, 25-26].

To avoid substituting one environmental problem for another, the consequences of using anionic detergents to reduce acid formation must be considered. The chronic and acute effects of anionic detergents on fish[27-28] and aquatic invertebrates[29] have been examined, with kidney damage observed after long exposure to low levels (2-15 mg/l) of detergent, and acute toxicity observed in some species at concentrations as varied as 0.6 - 40 mg/l. The World Health Organization recommends that stream concentrations not exceed 1.0 mg/l; other regulatory groups have recommended even lower values (e.g., Pennsylvania's Department of Environmental Resources, 0.25 mg/l).

Application Rates

To be effective in the field, surfactant must reach the reactive pyritic material. At a surface mine, excess surfactant must be applied to compensate for that which will be absorbed by non-pyritic overburden material. A refuse pile is somewhat to treat because surfactant can be applied directly to the pyritic material and because most acid production occurs near the surface of the pile, due to the presence of a fine-grained oxygen diffusion barrier[30]. Sufficient surfactant must be applied to treat this near-surface layer.

A simple laboratory procedure has been developed to provide an estimate of adsorption potential for overburden and coal refuse. A representative sample of the material to be treated is placed in a large, tared Buchner funnel, tamped to a uniform depth of two inches, and weighed. A surfactant, such as sodium lauryl sulfate (SLS), is applied evenly over the material at approximate loads of 60 mg of SLS per kg of coal refuse or 30 mg of SLS per kg of overburden and subsoil. Typical solution concentrations range from 300 to 30,000 mg SLS/l, depending on the anticipated infiltration rate at the site.

After SLS application, the top section of a second funnel is fitted onto the packed funnel to allow even distribution of a distilled water rinse. The rinse solution is continuously applied through plastic tubing from a distilled water reservoir. The height of the reservoir is adjusted to balance influent and effluent volumes; in relatively impermeable samples inundation is unavoidable and effluent flow rates can be as slow as 100 ml/hr. Rinse solution is collected in 100 ml fractions until no sudsing is observed on shaking.

The stock SLS solution and rinse fractions are analyzed for anionic surfactants by the methylene blue technique or a comparable standard method[31]. Adsorption is calculated as the difference between the mass of SLS applied and that eluted, and is recorded as mg of SLS adsorbed per kg sample. Alter-

natively, adsorption can be reported as lb SLS/acre-inch, calculated from the known funnel area and sample thickness.

The laboratory test provides a relative measure of adsorption capacity, since field conditions are not duplicated. On coal refuse, we base our application rate on the adsorptive capacity of the top 1 foot, knowing that the most active zone of oxidation is typically shallow and that surfactant, at reduced concentrations, will penetrate beyond this surface layer. We have been admittedly conservative rather than risk significant surfactant concentrations in the effluent; we will, in the future, be testing the effect of higher dosage rates.

If pyritic overburden is treated while exposed, application rates can be based on the adsorptive capacity of the material. However, if inert material has already been placed over the pyritic material, higher dosage rates must be applied to ensure that sufficient surfactant penetrates to the pyrite. To avoid surfactant runoff, areal application should not be attempted at sites where a clay blanket or compaction severely limit permeability; in addition, surfactants should only be applied during dry weather.

Field Tests

Based on laboratory results, it was apparent that anionic surfactants had the potential to slow down pyrite oxidation by inhibition of T. ferrooxidans. However, the possibility of repopulation remained. The required frequency of reapplication and the extent to which water treatment costs could be lowered would be the key factors in determining cost-effectiveness. Full-scale field tests were started in Fall, 1981 to answer these questions.

The first site chosen was a ten-acre inactive coal refuse pile in Raleigh County, WV. The pile was formed of Beckley seam refuse during the late nineteenth century by dumping from an aerial tramway. It is long and narrow and approximately 130 ft high at its crest. Drainage from the pile is currently being treated, at a cost of about $7,500 a month by Westmoreland Coal Company, which operates the nearby mine and preparation plant. Quality of the drainage from the pile has been monitored by Westmoreland for over a decade, thus providing a good baseline against which the effectiveness of the method could be judged.

The second field site selected was an active coal refuse pile in Preston County, WV. The pile consists primarily of Freeport seam refuse, from a preparation plant operated by Kingwood Mining Company. Inactive sections of the refuse pile are downgradient of the 8-acre active section and are revegetated; treatment of the drainage from the entire refuse area costs Kingwood Mining about $1,000 a month.

One problem with the Kingwood refuse site was the lack of background data for just the active section being treated. A channel was therefore constructed by Kingwood Mining to collect surface runoff from much of the treated area, thus providing some indication of whether the application of the surfactant improved water quality.

Coal refuse from both sites had an adsorption capacity of about 45 mg SLS/kg of material. This is equivalent to 154 lbs of SLS/acre-ft, or 1 drum (55 gallons) of 30% SLS solution per acre; a drum costs about $200. Both sites were treated by hydroseeder. At Westmoreland, the SLS was diluted approximately 500:1; at Kingwood, a shortage of good quality water resulted in using a dilution ratio of only 50:1. The Westmoreland site was treated in late September; the Kingwood site in early October. Water samples were collected at least once a week thereafter and routinely analyzed for sulfate, acidity, pH, iron and anionic surfactants.

At the active (Preston County) site, water quality improved dramatically within a month of the SLS application. Acidity, sulfate and iron were reduced by more than 95 pct and remained low for about four months after treatment (figure 2). A

Figure 2. Effect of sodium lauryl sulfate on run-off water quality at an 8-acre active coal refuse pile in northern West Virginia.

complicating factor at the site is untreated material which was added during that interval; it is impossible to separate out the effects of the acidification of the new refuse from the diminishing effects of the SLS.

Water quality at the inactive (Raleigh County) site improved after a three month lag period, with a 60% decrease in acidity, sulfate and manganese and a 90% decrease in iron (figures 3-6). The lag period was presumably caused by the time required for infiltration to flow through the old pile, but stored acidity (sulfate salts) in the system may also have been a factor. The obvious correlation between sulfate, acidity and manganese indicates that as acid production was reduced, leaching of trace metals such as manganese also decreased. The disproportionately greater decrease in iron appears to indicate that at least some of the refuse reached a pH high enough to precipitate ferric hydroxide within the pile.

Effluent concentrations of surfactant have been extremely low at both sites. Except for one measurement of 0.6 mg/l shortly after application of the SLS to the inactive pile, SLS concentrations have been consistently less than 0.1 mg/l; no SLS has been detected in the stream at the discharge point of either treatment plant.

Figure 3. Effect of sodium lauryl sulfate on acidity of drainage from a 10-acre inactive coal refuse pile in southern West Virginia.

Figure 4. Effect of sodium lauryl sulfate on sulfate concentrations at the southern West Virginia site.

Figure 5. Effect of sodium lauryl sulfate on manganese concentrations at the southern West Virginia site.

Figure 6. Effect of sodium lauryl sulfate on iron concentrations at the southern West Virginia site.

The surfactant treatment can also be used as a preventive measure. For the past three years, Barnes and Tucker Coal Co. has been applying SLS to an active refuse area using a road watering truck three times a year. The drainage from the area still shows a net alkalinity although their refuse piles generally become acid-producing within six months. Another company in central West Virginia is applying an anionic surfactant to their coal refuse as it leaves the preparation plant. A soil and vegetative cover will be placed on the refuse as soon as the pile is complete, and will, they hope, eliminate the necessity of retreatment.

However dramatic the results, field tests such as those described above are subject to external influence. We have therefore recently initiated several full-scale field tests in which experimental control is provided by a nearby hydrologically isolated, untreated area.

We have treated: one of two adjoining 30-acre surface mines in Preston County, WV; one of two adjoining coal refuse areas, containing refuse from the same preparation plant, in Monongalia County, WV; and one of two piles in a single refuse area in Marion County, WV. The results from some or all of these tests will be available for presentation at the conference.

Although active operations can be easily retreated as necessary, abandoned mined lands require a long-term solution. We have developed SLS-natural rubber compositions which slowly release SLS over time. The SLS is washed from the surface of the rubber whenever it is wet, with internal solution pressure causing migration of the surfactant through the elastic medium to the surface[32]. Ideally, surfactant release should last at least five years, to provide sufficient time for re-establishment of normal soil biota.

We have previously reported the results of pilot-scale tests in Pennsylvania and West Virginia[33]. A full-scale field test was initiated in July 1981 in eastern Ohio on a well-studied inactive surface mine. The area was mined between 1968 and 1970, exposing a pyritiferous sandstone overburden in a series of ridges and valleys. One 12 acre section, with a known flow-through time of 15-18 months[34] was treated by seeder with approximately 18 gallons of 30% SLS solution per acre and 1,500 lbs of SLS-impregnated rubber pellets. The effect of the treatment should be observed during Fall, 1982 and will be reported at the conference.

A second field test is currently underway at an active mine site in Upshur County, WV. An isolated 15-acre ridge has been divided into three sections in such a way that the drainage from each area can be monitored. The operator is using state-of-the-art reclamation practices, including the use of an inert pad, application of alkaline material to the pyritic overburden and the covering of the pyritic material with clayey soil, more inert material and topsoil. One section will be treated with the SLS-impregnated rubber pellets, at a rate of about 400 lbs/acre, and SLS solution at a rate of 55 gallons/acre. A second section will be treated with just the SLS solution, the third section will provide experimental control.

As mentioned in an earlier paper[32], we are attempting to optimize release characteristics of the rubber to provide low-cost long-term treatment. We are currently testing a new formulation developed by B. F. Goodrich which contains over twice as much SLS as rubber; if release lifetime is not adversely affected by the loading, a product may be commercially available by early 1983.

Summary

Application of an anionic surfactant to active and abandoned coal refuse areas reduced acid drainage 60-95 pct by inhibiting the bacterium, Thiobacillus ferrooxidans. Parallel decreases in sulfate and acidity confirmed that the actual acid formation mechanism was affected. Due to reduced acid dissolution, trace metal concentrations also fell concordantly. Iron concentrations decreased disproportionally, indicating that precipitation of iron hydroxide is probably occurring with the refuse piles.

Additional field tests are in progress to evaluate the applicability of the method to active and abandoned surface mines and the possibility of long-term control of acid production by slow release of the anionic surfactant from an elastomer.

Report of Investigations 8847

Control of Acid Drainage From Coal Refuse Using Anionic Surfactants

By Robert L. P. Kleinmann and Patricia M. Erickson

ABSTRACT

To control the formation of acid drainage at its source, the Bureau of Mines has investigated the role of iron-oxidizing bacteria in the oxidation of pyrite. In laboratory tests, it was determined that Thiobacillus ferrooxidans could be controlled in coal refuse using anionic surfactants, with an associated decrease in acid production of about 75 pct. Based on these results, large-scale tests were conducted at an 8-acre active coal refuse area in northern West Virginia and an 11-acre inactive refuse pile in southern West Virginia. Acid production was decreased 60 to 95 pct for 4 to 5 months after application of 55 gal/acre of 30-pct sodium lauryl sulfate solution. To date, effluent surfactant concentrations have been extremely low.

Either a hydroseeder or a road-watering truck can be used to apply the surfactant. Since the surfactant solution must reach the pyritic material to be effective, sites that have been reclaimed are generally not amenable to these procedures. A simple laboratory test is described that provides an estimate of adsorption potential; this can be used to calculate a safe application rate.

INTRODUCTION

The exposure and subsequent oxidation of iron sulfide minerals causes the acidic drainage associated with many coal mines and refuse piles. To meet State and Federal discharge regulations, mining companies spend millions of dollars annually to treat acid water. The Bureau of Mines has investigated possible methods of lowering these costs by slowing the rate of pyrite oxidation, thereby controlling the problem at its source.

The kinetics of acid formation are dependent on the availability of oxygen, the surface area of pyrite exposed, the activity of iron-oxidizing bacteria, and the chemical characteristics of the influent water. Thiobacillus ferrooxidans is the principal iron-oxidizing bacterium involved in pyrite oxidation (29, 35).[3] Acidification progresses in a three-stage sequence dependent upon the activity of T. ferrooxidans and solution Eh and pH (30).

One potential method of slowing pyrite oxidation is by inhibition of T. ferrooxidans. Certain anionic surfactants (cleansing detergents) can be used to kill T. ferrooxidans at low pH (13, 30) in an economical and environmentally safe manner, thus reducing acid formation. This report presents the results of treating coal refuse with an anionic surfactant. It also includes a procedural guide for determining if the surfactant treatment is appropriate for a specific site and a method of calculating application rates. Future reports will discuss the treatment of pyritic mine spoil and incorporation of the surfactant into slow-release formulations for long-term control of the problem.

ACKNOWLEDGMENT

The laboratory work described on pages 4-5 was conducted by R. Kleinmann as part of his graduate studies at Princeton University. The financial support contributed by Princeton University, technical assistance provided by E. Mohring, graduate student, University of Minnesota, and geochemical advice provided by D. Crerar, associate professor, during that period are gratefully acknowledged. We also thank Westmoreland Coal Co., Raleigh County, WV, and Kingwood Mining Co., Preston County, WV, for their cooperation.

BACKGROUND INFORMATION

THE PYRITE OXIDATION SYSTEM

The possible involvement of bacteria in the formation of acid drainage was first reported in 1919 by Parr and Powell, who determined that coal inoculated with an unsterilized ferrous sulfate solution produced drainage with higher concentrations of sulfate than did sterile controls (37). The isolation of the bacteria responsible did not take place until 1947 (10-11), at which time it was proposed that Thiobacillus thiooxidans accelerated pyrite oxidation, whereas T. ferrooxidans (47) merely accelerated iron oxidation. Later studies revealed that T. ferrooxidans could also significantly accelerate pyrite oxidation (48) and that in fact T. thiooxidans could not (35). Other bacteria similar to T. ferrooxidans and capable of accelerating pyrite oxidations were isolated and named Ferrobacillus ferrooxidans (36) and Ferrobacillus sulfooxidans (26). However, these were later judged to be strains of T. ferrooxidans (9, 51).

T. ferrooxidans actually accelerates pyrite oxidation by two mechanisms: by direct oxidation and by oxidizing Fe^{2+} to Fe^{3+}, which in turn oxidizes the sulfide minerals (6, 15, 21, 43). Direct

[3]Underlined numbers in parentheses refer to items in the list of references at the end of this report.

bacterial oxidation of pyrite is generally slower than the indirect process (52), although some strains and adapted cultures display the opposite tendency (18). Direct oxidation is probably most important during initial acidification, when complete hydrolysis of Fe^{3+} and the resultant precipitation of $Fe(OH)_3$ are too rapid to allow ferric iron to act as an important oxidant.

During the first stage of this process, fine-grained pyrite is oxidized either by T. ferrooxidans or by air with equal amounts of acidity produced by the oxidation of sulfide to sulfate (reaction A) and by the oxidation and hydrolysis of iron (reaction B) (5):

$$FeS_2 + \frac{7}{2} O_2 + H_2O \longrightarrow Fe^{2+} + 2SO_4^{2-} + 2H^+; \quad (A)$$

$$Fe^{2+} + \frac{5}{2} H_2O + \frac{1}{4} O_2 \longrightarrow Fe(OH)_3(s) + 2H^+. \quad (B)$$

The ability of T. ferrooxidans to accelerate the rate of pH decline is important, for each rainfall potentially interferes with the initial buildup of acid. As long as alkalinity exceeds acidity, the only major downstream effect is an increase in sulfate concentration. Once acidity significantly exceeds alkalinity, it becomes difficult to return the acid-producing system to stage 1.

As the pH decreases, abiotic oxidation of Fe^{2+} slows down dramatically, according to the rate law:

$$\frac{-d\,(Fe^{2+})}{dt} = k\,\frac{(O_2\,(aq))\,(Fe^{2+})}{(H^+)^2}, \quad (1)$$

where (Fe^{2+}), $(O_2\,(aq))$, and (H^+) are activities, k is the rate constant, and t is time (46).

As the abiotic rate decreases, T. ferrooxidans assumes its primary role of oxidizing Fe^{2+}, thereby allowing reaction B to continue producing acidity and ferric hydroxide. Although the reaction stoichiometry remains the same, this step is defined herein as a transition point from the primarily abiotic stage 1 to the bacterial catalysis-controlled stage 2. Eliminate T. ferrooxidans and the pyritic system will stabilize. Otherwise, the pH decline typically continues to stage 3, where the reaction chemistry changes to a biologically mediated cycle of reactions C and D (30, 48):

$$Fe^{2+} + \frac{1}{4} O_2 + H^+ \longrightarrow Fe^{3+} + \frac{1}{2} H_2O; \quad (C)$$

$$FeS_2 + 14Fe^{3+} + 8H_2O \longrightarrow 15Fe^{2+} + 2SO_4^{2-} + 16H^+. \quad (D)$$

As acidification proceeds and the pH in the immediate vicinity of the pyrite falls to less than 3, the increased solubility of iron and the decreased rate of $Fe(OH)_3$ precipitation result in increased Fe^{3+} activity (43). At an interstitial pH of approximately 2.5 (corresponding to a drainage pH of 3.5 to 4.0), bacterial oxidation of Fe^{2+} and reduction of Fe^{3+} by the pyrite (reactions C and D) combine to cause a dramatic increase in acidity and iron concentrations, as can be seen in figure 1. Eliminating the bacteria halts this third stage and thus reduces acid production.

The possibility of reducing acid drainage by bacterial inhibition was first considered in 1953 but was rejected as impractical due to probable rapid repopulation (34). Later attempts to inhibit T. ferrooxidans in the field or in large-scale laboratory experiments were unsuccessful (5, 42), which supported this viewpoint. Despite the results of these early attempts, it was felt that the crucial role played by T. ferrooxidans in pyrite oxidation warranted a reexamination of the potential use of bactericidal methods in mining environments.

FIGURE 1. - Acidity and total dissolved iron versus pH for a series of experiments conducted in laboratory simulations of a coal refuse pile (28).

The biological literature contains numerous laboratory inhibition studies of T. ferrooxidans conducted in attempts to understand the unusual biochemistry of its metabolism. These studies demonstrated the vulnerability of T. ferrooxidans to certain metals (such as mercury, tellurium, and molybdenum), organic acids, and some anionic surfactants (13, 25, 41, 49-50). After eliminating substances that were environmentally unsafe or too expensive for large-scale use, it was decided to test anionic surfactants. These surfactants, used as cleansers in laundry detergent and shampoos, fill T. ferrooxidans in culture medium at concentrations as low as 2 to 5 mg/L (13-14, 28).

INHIBITORY EFFECTS OF ANIONIC SURFACTANTS

Anionic surfactants are generally regarded as good cleansers but poor bactericides (54). However, it has been shown that their ability to inhibit bacterial activity increases markedly at low pH (16). The various means by which surfactants affect microorganisms have been summarized by Hugo (24), who concluded that alteration of the semipermeable properties of the cytoplasmic membrane is the most typical mode of inhibitory action. This view is supported by demonstrated disaggregation of cell walls of other bacteria by the interaction of sodium lauryl sulfate (SLS) with the lipid, lipoprotein, and lipopolysaccharide fractions of the cell wall (40). T. ferrooxidans possesses a multilayered cell wall, which allows it to maintain an approximately neutral internal pH despite the extremely acid environment in which it lives (3, 7, 12, 23, 33). At low concentrations, it appears that anionic surfactants induce seepage of H^+ into the cell, which slows Fe^{2+} oxidation by decreasing the activity of pH-sensitive enzymes. Higher concentrations of the surfactant kill the bacteria, presumably by causing permanent damage to these enzymes and the membrane material (13, 22, 28, 38).

LABORATORY TESTS

Inhibitory effects of anionic surfactants were monitored in the laboratory under humid conditions simulating the intermediate belt of the zone of aeration as described in Kleinmann and Crerar (29), using 50-g samples of crushed, rinsed, and sterilized high-sulfur coal. To simulate the presence of T. ferrooxidans in natural mine infiltration, a 0.1-mL inoculum of a pure culture of the bacteria, in 9K medium (44), was trickled onto the samples every 3 days. Immediately following this, 0.6 mL of water with varying concentrations of surfactant was applied. Sterile controls received no inoculum.

Figure 2 shows the effect of four of the anionic detergents on acidity and dissolved iron. The inhibitory effect was especially marked for SLS, which was also the most effective in limiting bacterial population. Samples containing SLS at concentrations from 5 to 20 ppm showed proportionally delayed growth when transferred to 9K culture medium; at 25 ppm SLS was bactericidal, with acidity and iron concentrations reduced to about those of sterile controls. Other anionic detergents required somewhat higher concentrations to obtain the same effects (fig. 2). Generally, about 10 times more surfactant was required to kill T. ferrooxidans in coal refuse than in 9K culture media (28).

Possible inhibition of inorganic pyrite oxidation by anionic detergents was also investigated (28). Table 1 presents the results of a 22-day experiment using the crushed, sterilized pyritic coal refuse and SLS concentrations up to 50 mg/L applied at 5-day intervals. In addition, one experimental pair received 50 mg/L $FeCl_3$ with each application, as a test for inhibition of ferric oxidation of pyrite. At the end of the experiment, the coal was filtered and rinsed with 100 mL of deionized, distilled water. Acidity and iron analysis of the filtrate and the drainage collected during the experiment indicated that the SLS did not significantly affect direct (air) oxidation or abiotic ferric oxidation of pyrite.

FIELD TESTS

INITIAL CONSIDERATIONS

Laboratory and pilot-scale tests (28-30) indicated that anionic surfactants had the potential to slow down pyrite oxidation by inhibiting T. ferrooxidans. Full-scale tests were needed to determine the effectiveness of the method under field conditions. Of particular interest were the degree to which water quality could be improved and the application frequency needed to control pyrite oxidation.

An immediate problem was determining an application rate for the field sites. Application at the inhibitory concentration determined in the laboratory (25 mg/L SLS) was clearly too low: Infiltration from the next rainfall would dilute the surfactant and allow repopulation. Adsorption of SLS on the spoil or refuse also had to be considered since relative adsorption and desorption rates would control pore water SLS concentration and the rate of SLS migration. The application frequency would also depend on the rate of SLS loss by hydrolysis in the acid environment and by biodegradation.

It was decided that initial application rates would be based on the amount of SLS that could be adsorbed within the top 1 ft of refuse. A procedure for estimating this adsorption capacity is described on pages 10-11. The 1-ft-thick treatment zone was selected for several reasons: (1) Oxidation was assumed to occur largely in a near-surface oxygenated zone (17, 20), (2) desorption would subsequently allow downward migration, and (3) it was preferred to undertreat rather than overtreat, to prevent significant SLS concentration off the site. Although SLS is generally regarded as safe for household use, it can have deleterious effects on aquatic life at relatively low concentrations (1-2, 8).

The surfactant is generally shipped as a 30-pct solution and must be diluted on-site. Site-specific factors, such as availability of water and infiltration-runoff characteristics, determine how much the surfactant is diluted.

INACTIVE REFUSE AREA TEST

The first site chosen was an 11-acre inactive coal refuse pile in Raleigh County, WV. The pile was formed of Beckley Seam refuse during the late 19th century by dumping from an aerial tramway. It is 1,500 ft long, 450 ft wide, and approximately 130 ft high at its crest. Quality of the drainage from the pile has been monitored by Westmoreland Coal Co. for over a decade, thus providing a good baseline against which the effectiveness of the method could be judged.

The adsorptive capacity of the coal refuse was determined to be about 45 mg SLS/kg of material, using the procedure described on pages 10-11. This is approximately equivalent to 150 lb SLS/acre ft, or 1 drum (55 gal) of 30-pct SLS per acre. The site was treated during late September 1981 with 10 drums of 30-pct SLS, diluted 175:1 (fig. 3). Water samples were collected at least once a week thereafter and routinely analyzed for sulfate, acidity, pH, iron, and anionic surfactants (4).

Water quality improved after a 3-month lag period, with a 60-pct decrease in acidity, sulfate, and manganese and a 90-pct decrease in iron (figs. 4-7). The lag period was presumably caused by the time required for infiltration to flow through the old pile, but stored acidity in the form of sulfate salts may also have been a factor. Seasonal effects can be discounted since in previous years the contaminant concentrations peaked in winter. The magnitude of the improvement was greater than any change observed over the past 10 years. The obvious correlation between sulfate, acidity, and manganese indicates that as acid production was reduced, leaching of trace metals such as manganese also decreased. The disproportionately greater decrease in

FIGURE 3. - Hydroseeder being used to spray sodium lauryl sulfate on 11-acre refuse area in southern West Virginia. Application rate: 55 gal/acre of 30-pct solution, diluted 175:1.

iron appears to indicate that at least some of the refuse reached a pH high enough to precipitate ferric hydroxide within the pile.

Before application of the SLS, Westmoreland Coal Co. was spending about $7,500 per month to treat the drainage from this pile. Based on the observed improvement in water quality and the costs of the SLS application, reduced water treatment costs paid for the SLS application in about 3 weeks.

ACTIVE REFUSE AREA TEST

The second field test was at an active coal refuse area in Preston County, WV. The pile is primarily Freeport Seam refuse from a preparation plant operated by Kingwood Mining Co. Inactive sections of the refuse pile are down gradient of the 8-acre active section and are revegetated; treatment of the drainage from the entire refuse area costs Kingwood Mining about $1,000 per month.

One problem with the Kingwood refuse site was the lack of background data for the active section being treated. A pond was therefore constructed by Kingwood Mining Co. to collect surface runoff from much of the treated area, thus providing some indication of whether the application of the surfactant improved water quality.

Adsorption tests indicated that an application rate of 1 drum per acre was again appropriate. The area was treated in early November 1981, using a hydroseeder, with a dilution factor of 50:1 (due to a shortage of good-quality water).

FIGURE 4. - Effect of sodium lauryl sulfate on acidity of drainage from 11-acre inactive coal refuse pile in southern West Virginia.

FIGURE 5. - Effect of sodium lauryl sulfate on sulfate concentrations at the southern West Virginia site. Lowered sulfate concentrations demonstrate that the acid production is being controlled at the source.

FIGURE 6. - Effect of sodium lauryl sulfate on manganese concentrations at the southern West Virginia site. By reducing acid production, dissolution of trace metals is decreased.

FIGURE 7. - Effect of sodium lauryl sulfate on iron concentrations at the southern West Virginia site. The disproportionate decrease in iron probably indicates that areas of the refuse pile are alkaline enough to result in iron hydrolysis and precipitation.

Water quality improved dramatically within a month of the SLS application. Acidity, sulfate, and iron were reduced by more than 95 pct and remained low for about 4 months after treatment (fig. 8). A complicating factor at the site is untreated material which was added during that interval; it is impossible to separate out the effects of the acidification of the new untreated refuse from the diminishing effects of SLS.

Effluent concentrations of surfactant have been extremely low at both sites. Except for one measurement of 0.6 mg/L shortly after application of the SLS to the inactive pile, SLS concentrations have been consistently less than 0.1 mg/L; no SLS has been detected in the stream at the discharge point of either treatment plant.

PROCEDURAL RECOMMENDATIONS

As a result of previously published articles by the authors (27, 31-32), the mining industry has started using anionic surfactants on coal refuse, coal stockpile areas, unreclaimed mine spoil, and waste sulfide rock. At present, more than 50 mining companies are using the technique with varied success. One coal company has applied an anionic surfactant two or three times a year to a developing coal refuse area for 4 years. The drainage is still showing net alkalinity, despite the fact that the coal refuse typically produces acidic drainage within 6 months. At the other extreme are sites where the technique produced no apparent effect or only a short-term improvement in water quality. Some of these failures can be explained simply, such as when the dosage rate or site conditions were obviously inappropriate. At other sites it may never be known why the technique failed to reduce acid production, although possible reasons are discussed

FIGURE 8. - Effect of sodium lauryl sulfate on runoff water quality at 8-acre active coal refuse pile in northern West Virginia. Application rate: 55 gal/acre of 30-pct solution, diluted 50:1.

below. Generally however, the technique has been successful. To improve the success rate, the following procedure is recommended.

PRELIMINARY CONSIDERATIONS

The first step in deciding if the surfactant technique is appropriate for a specific site is determining if it is potentially cost effective. Assume for the moment an approximate annual material cost for surfactant of $600 per acre. Add to that the cost of three applications, the expense of which will vary from site to site. One should consider, for example, whether the surfactant will be applied with equipment already on-site and using available personnel time or with contracted equipment and manpower. For potential savings, assume a 60-pct decrease in acidity; this will reduce neutralization costs by about the same amount. If a 90-pct decrease in sludge accumulation is further assumed, one can estimate an associated annual savings based on the frequency with which the pond is normally cleaned. Other treatment costs, such as equipment and operator expenses, will generally not decrease significantly since the volume of water to be treated stays the same.

Since the surfactant must reach the pyritic material to be effective, the presence of intervening overburden or topsoil will clearly reduce the effectiveness of the treatment. If the cover is highly permeable, treating with somewhat higher levels of surfactant will compensate; if not, the surfactant will probably all be adsorbed by the nonpyritic material or will be washed away in surface runoff. Several mine operators have recently tried to solve this problem by applying the anionic surfactant solution through shallow wells; it is too early to judge if they have been successful.

If quick results are required, two other factors must be considered: hydrologic flow-through time and ground water pools. Flow-through time is the time it takes for rainwater to infiltrate through the mine material and emerge in a spring or seep. In mine spoil, flow-through times of over a year have been measured (19). In such a case, improvement in water quality at the discharge point cannot occur faster than water flows through the material.

Ponding of acid water on the old mine floor or in a refuse area also retards or masks the effect of reduced acid production. The presence of such a pool can sometimes be surmised by a steady acid load in the base flow during dry periods and only slight changes in the acid load during higher flows. If the pool volume is significant, it could be years before a decrease in acid production is reflected by more than a gradual improvement in water quality. If faster results are desired, alkalinity must be added to the pool in sufficient quantities to neutralize all of the acidity present.

APPLICATION PROCEDURES

If, based on the above considerations, the site appears appropriate for the surfactant treatment, the obvious question is how much surfactant is required. As described earlier, the concentrations needed to kill T. ferrooxidans in small volumes of coal refuse are quite low (25 to 40 mg/L). Such an application would be ineffective at an actual mine site because it would fail to reach most of the oxidizing pyrite. It is necessary to determine the adsorption capacity of the material being treated and to compensate for that adsorption with extra surfactant.

A simple laboratory procedure has been developed to provide an estimate of adsorption potential for overburden and coal refuse. A representative sample of the material to be treated is placed in a large, tared Buchner funnel, tamped to a uniform depth of 2 in, and weighed. A surfactant, such as SLS, is applied evenly over the material at approximate loads of 60 mg SLS/kg of coal refuse. Typical SLS concentrations range from 300 to 30,000 mg/L and are selected on the basis of the anticipated infiltration rate.

After the surfactant application, the top section of a second funnel or a perforated plate is fitted onto the packed funnel to allow even distribution of a distilled water rinse. The rinse solution is continuously applied through plastic tubing from a distilled water reservoir. The height of the reservoir is adjusted to balance influent and effluent flow rates; in relatively impermeable samples inundation is unavoidable and effluent flow rates can be as slow as 100 mL/h. Rinse effluent is collected in 100-mL fractions until no sudsing is observed on shaking.

The stock SLS solution and rinse fractions are analyzed for anionic surfactants by the methylene blue technique or a comparable standard method (4). Adsorption is calculated as the difference between the mass of SLS applied and that eluted and is recorded as milligrams of SLS adsorbed per kilogram of sample. Alternatively, adsorption can be reported as pounds SLS per acre inch, calculated from the known funnel area and sample thickness.

The laboratory test provides only a relative measure of adsorption capacity, since field conditions are not duplicated. On coal refuse, we base our application rate on the adsorptive capacity of the top 1 ft, since the most active zone of oxidation is typically shallow, and since surfactant, at reduced concentrations, will penetrate beyond this surface layer. We have been deliberately conservative to avoid the risk of significant surfactant concentrations in the effluent; we will test the effect of higher dosage rates in the future.

At sites where the pyritic material is not exposed, excess surfactant must be applied to compensate for that which will be adsorbed by the overburden. The adsorption rate can be determined using the procedures described and by assuming that the adsorptive capacity of the entire column must be accounted for. The extent of oxidation in buried pyritic spoil and refuse has not been determined, making it difficult to determine how much surfactant should be allotted for the actual acid source. Research is underway to determine oxygen concentrations at depth in coal refuse and mine spoil, which should help answer this question.

Based on adsorption tests conducted to date, application rates generally range from 1/4 to 1 drum of 30-pct SLS per acre. It is necessary to dilute the surfactant solution both to provide sufficient coverage and to allow for infiltration; the optimal dilution ratio is site specific. At low dilution rates (less than 125:1), application rates should be increased slightly to compensate for higher adsorption rates; also, excessive foaming can be a problem. Ideally, a dilution of 500:1 or even greater would be best, but in practice this would result in surfactant solution flowing over land as runoff, and in significantly higher labor costs.

Both hydroseeder and road watering trucks have been used by mine operators for application of the surfactant solution. With either machine, it is important to add the water to the tank at the bottom (using a hose) to avoid excessive foaming. For the same reason, agitation should be avoided as much as possible. Care should be taken when dealing with the concentrated surfactant; gloves should be worn to avoid "dishpan hands," and contact with the skin and eyes should be avoided. Finally, it is recommended that the tank and hoses be thoroughly rinsed of all surfactant after the application is completed, as the concentrated solution can cause pitting if allowed to remain.

OTHER CONSIDERATIONS

In the field tests and laboratory work, SLS was used rather than other anionic surfactants. There were two reasons for the initial choice: SLS inhibited *T. ferrooxidans* at lower concentrations than other generally available surfactants tested, and it hydrolyzes and breaks down in an acid environment. It was felt that these two factors would reduce the likelihood of significant contamination in

the receiving stream. High adsorption, which was not initially considered, has probably contributed to the fact that effluent surfactant concentrations have been extremely low. We have, however, continued to use SLS in our field tests rather than introduce other variables. Some may wish to test other anionic surfactants, such as linear alkyl benzene sulfonate and alpha olefin sulfonate, which require somewhat higher concentrations to effectively inhibit T. ferrooxidans but which are less expensive and less acid sensitive than SLS. The latter factor may be especially important on refuse areas where the surface pH is very low; it is possible that in such a case SLS may lose its effectiveness by hydrolyzing before it contacts most of the oxidizing pyrite. Experiments are in progress to find acid-resistant surfactants that are equal to or more effective than SLS in inhibiting T. ferrooxidans (39, 45).

Reapplication of the surfactant is normally required to replace what is desorbed or degraded. When material from an exposed refuse area was tested 2 months after treatment, virtually no surfactant was found in the top 1 ft, although some surfactant remained below that level. In contrast, at another site that had been topsoiled and revegetated immediately after application of the surfactant, and from which there was virtually no subsurface drainage for about 18 months, enough surfactant remained to cause visible sudsing when, after 2 months of heavy rainfall, ground water reached the surface.

Potential consequences of using anionic detergents to reduce acid formation must be considered so as to avoid substituting one environmental problem for another. Studies of the chronic and acute effects of anionic detergents on fish and aquatic invertebrates indicate that kidney damage occurs in fish after long exposure to low levels (2 to 15 mg/L) of detergent, and that acute toxicity occurs in some species at concentrations as varied as 0.6 to 40 mg/L (1-2, 8). The World Health Organization recommends that stream concentrations not exceed 1.0 mg/L; other regulatory groups have recommended even lower values (e.g., Pennsylvania's Department of Environmental Resources, 0.25 mg/L). As stated earlier, effluent concentrations of SLS at the Bureau's field sites have been very low, typically below 0.1 mg/L in the effluent and below detectable limits in the receiving stream. The laboratory procedure to determine the application rate is apparently effective in preventing overtreatment; the only remaining concern is surfactant concentrations in the runoff. To minimize this risk, it is recommended that the surfactant be applied only when the ground is unsaturated and when no major rainstorms are expected for several days.

The surfactant solution has been sprayed onto revegetated sites with no apparent adverse effects on vegetation. It is recommended that treatment predate seeding by several weeks. It should similarly be in advance of any lime applications, as that might diminish the effectiveness of the surfactant.

CONCLUSIONS

1. Thiobacillus ferrooxidans plays an important role in determining the rate of pyrite oxidation. Anionic surfactants, applied at concentrations greater than 25 mg/L, reduce this bacterial activity and thereby slow acid production.

2. A laboratory procedure has been developed to determine suitable application rates for a specific site. Based on existing field data, the procedure appears to be effective in preventing overtreatment. Surfactant concentrations have generally been less than 0.1 mg/L in the effluent from the treated areas.

3. Sodium lauryl sulfate was applied to an 11-acre inactive coal refuse pile in southern West Virginia at a material cost of about $200 per acre. Acid

production fell approximately 60 pct, with an associated 90-pct decrease in iron concentration.

4. An 8-acre active coal refuse area in northern West Virginia was similarly treated. Acid production fell approximately 95 pct, with an associated 95-pct decrease in iron concentration.

5. At sites where water treatment costs are high, application of an anionic surfactant should be considered. Surfactant application should be repeated three times a year for maximum benefit.

Abstract. It has been previously demonstrated that anionic detergents inhibit the bacteria T. ferrooxidans which otherwise catalyze the formation of acid drainage from pyritic material. Liquid sprays of these detergents are effective for short periods of time and are useful in satisfying overburden adsorption capacity and in initial rapid inhibition of bacteria. For a permanent solution, controlled release systems are needed to provide the required concentration of detergent over prolonged periods of time sufficient to permit healthy growth of vegetation on the reclaimed overburden. A good ground cover, when sustained over a period of years, will eventually deprive the spoil of oxygen and water needed to generate acidity. Different materials and configurations for obtaining desired rates of release of anionic detergents are described. Laboratory tests have been developed to analyze the release rates of the controlled release materials. These tests are used to determine application rates. Field trials have been conceived to verify application theories and to demonstrate long term effectiveness of these materials together with their biodegradability to insure that one environmental problem is not replaced by another. Laboratory and field tests are described and discussed.

Introduction

Acid mine drainage occurs as a result of the oxidation of ferrous sulfides such as pyrite and marcasite and is catalyzed by the bacteria Thiobacillus ferrooxidans. A pH dependent three stage mechanism of acid generation has been proposed.[1] Numerous substances have been tested and found to be inhibitory or toxic to T. ferrooxidans.[2-10] Of the compounds tested, anionic detergents, particularly sodium lauryl sulfate (SLS), have been shown to be inhibitory at concentrations on the order of 10^{-6} M in culture media[8] and in mine spoils at somewhat higher concentration.[11] Sodium lauryl sulfate has the additional benefits of being low in mammalian toxicity[12] and quite biodegradable[13] so subsequent environmental problems are unlikely.

Spray application of SLS solution inhibits acid production of refuse piles for approximately four months.[14] Sulfate and iron levels are also reduced. As the SLS degrades or is lost due to runoff, the bacteria repopulate and acidification and resultant high iron and sulfate levels again occur. To bypass the inherent short effectiveness period of spray applications, Kleinmann[15] proposed and evaluated a controlled release form of SLS contained within the rubber matrix. He found that a combination of SLS solution spray and controlled release solid SLS resulted in major reductions of acidity, iron, and sulfate levels in drainage from a refuse pile (compared to a control) for a period of about one year.

To insure successful reclamation, that is, returning water quality to its premining condition for pH, total sulfate and total iron concentrations, bacterial inhibition longer than one year is desired. Acid generated in the early phases of reclamation can cause acid percolation to the surface resulting in the destruction of vegetation. If a lush vegetative cover can be maintained for about five years the acid production cycle might be permanently broken due to three natural biological processes. (1) As a healthy root system is established it competes for both oxygen and moisture with potentially acid-producing bacteria. (2) Populations of beneficial heterotrophic soil bacteria and fungi are reestablished resulting in the formation of organic acids which are inhibitory to T. ferrooxidans.[10] (3) The action of these heterotropic bacteria increases CO_2 levels in the groundwater resulting in increased solubilities of neutralizing calcareous materials. Reclamation has been shown to return pH and iron levels to near premining levels.[16]

Figure 1. a. Hypothetical application of sodium lauryl sulfate as a spray and in controlled release form. Spray applications provide an effective dosage quickly but the concentration falls rapidly. To maximize the effective lifetime of a spray application it is necessary to overdose the system initially. Controlled release systems maintain the dosage in the proper range but there is a significant delay between application and attainment of an effective dose. b. To prevent initial overdosing and inadequate concentrations just prior to reapplications it is necessary to respray smaller doses more frequently.

Figure 2. a. Level of SLS due to an initial spray application and due to a controlled release application. b. By carefully tailering the initial spray applications and controlled release system the level of SLS can be maintained nearly constant from the initial application onward.

Controlled Release Technology

It has already been noted that spray applications of SLS effectively inhibit mine acid formation for three or four months and simple controlled release systems for up to about one year. Figure 1 shows a hypothetical scenario relating spray applications to ideal controlled release application of detergent.

Spray applications have the advantage of delivering an effective dose of the active agent quickly, but the level falls rapidly due to runoff and biodegradation. To maximize the duration of effectiveness using a spray application it is necessary to use large amounts of the agent resulting in potential environmental problems (Figure 1a). Decreasing the dosage minimizes the potential environmental problems but increases the application frequency required (Figure 1b). A potential disadvantage of controlled release is the long time interval between application and attainment of the minimum effective concentration. The primary advantage however is that once an effective concentration is attained it can be maintained for extended periods using less total active agent. The removal processes (biodegradation, degradation, hydrolysis, photolysis, leaching etc.) following spray application follow first order kinetics;[17]

$$t_e = \frac{1}{k_r} \ln \frac{M_\infty}{M_e} \qquad (1)$$

where t_e is the time an effective level is maintained, k_r is the rate constant for removal, M_∞ is the initial amount of agent applied and M_e is the minimum effective amount. Thus, increasing the duration of effectiveness requires an exponential increase in the initial application. Maintaining an effective concentration using a controlled release system results in a greatly enhanced duration of effectiveness as follows:[17]

$$t_e = \frac{M_\infty - M_e}{k_D M_e} \qquad (2)$$

where k_D is the rate constant for delivery from the controlled release device.

Figure 2 shows how a combined initial SLS spray application and controlled release system can be utilized to get an immediate effective dose and long term effectiveness without the danger of overapplication nor the need for frequent reapplication. The initial spray application required is dependent not only on the concentration required to kill acid producing bacteria, but on the capacity of the overburden to adsorb SLS. This aspect has been dealt with elsewhere.[14]

Among the various factors which must be considered in the design of a controlled release system for sodium lauryl sulfate are the choice of the polymer system and its interaction with the active agent. The polymer must be capable of incorporating the agent either by solution or as a heterogeneous blend in which particles of the SLS are contained within the polymer matrix. Furthermore, the polymer - SLS - system should not chemically alter the SLS, but rather should act as safe harbor for the active agent until release occurs. The polymer system and any additives present must be harmless to the environment and preferably be themselves biodegradable after the useful lifetime of the product is complete. The chemical and physical environment must be considered when developing controlled release systems. The system must be functional in the environment for which its use was intended, conditions which frequently vary from idealized conditions generally employed in the laboratory. The controlled release system must be designed in such a way as to be applicable in the field providing uniform coverage over infected areas with the ability to remain active at the site for the desired lifetime of the product. Some specific factors which should be taken into account in the development of a controlled release product are reviewed in Table I.

Table I. Some specific factors which must be taken into account in developing a controlled release system.

- Chemical environment
  - pH, acidity, sulfates, iron
  - Moisture content
  - Pyrite content
- Physical Environment
  - Particle size distribution
  - Soil cover
  - Slope
  - Accessability (application)
  - Degree of vegetation
  - Type of overburden material
  - Spoil age - stage of acid production
- Climatological
  - Precipitation (average, events)
  - Temperature - (average and extremes)
- Hydrologic
  - Percolation rates
  - Runoff rates
  - Transpiration rate

The Process of Diffusion

A controlled release device basically consists of a reservoir of active agent which is systematically metered into the environment of intended use over a prolonged period of time. For mine acid control applications the system must consist of small, self contained units which can be easily distributed over the treatment area. The reservoir system can conveniently consist of a membrane coating over the active agent or a membrane coating over a polymer core containing dispersed or dissolved agent or a combination of these. Diffusion, osmotic pressure or bioerosion can be utilized to release the active substance from the reservoir system.

The process of diffusion is perhaps the simplest means of regulating release. Diffusion in polymer systems has been recognized as an important process since Graham[18] first observed the diffusion of a gas through a rubber membrane in 1829. Diffusion is the net transport of matter by means of random molecular motion, resulting in the removal of a chemical potential difference in a system leading eventually to equilibrium. The ability for a substance to diffuse through a polymer layer is related to the solubility and molecular mobility of the substances and follows Ficks laws for rubbery materials.[19,20]

Basic Concepts of Controlled Release

A number of concepts have been employed for controlled release and have been extensively discussed.[21] For the purpose of this paper we will briefly discuss the release characteristics of two major options available for controlled release treatment of acid mine drainage. These are the membrane bound reservoir system and the monolithic system.

For rate controlling membrane bound reservoir systems, where the concentration of release agent at the membrane reservoir interface is constant, Ficks law predicts that the release rate will be constant and independent of time and geometry. Thus

$$M_t = kt \qquad (3)$$

where M_t is the amount of agent released, t is time and k is the release rate. In treating mine spoils, ideal release kinetics may not be realized due to changing boundary conditions resulting from various climatic factors such as variable rates of precipitation.

Reservoir systems without rate controlling membranes follow $t^{1/2}$ order release kinetics such that

$$M_t = kt^{1/2} \qquad (4)$$

Such systems give initially large release rates followed by much slower rates during the last part of the product life.

Non-erodible monolithic systems consist of a physical blend of active substance in a polymer matrix with the polymer acting to control the release of the substance. The active agent may be either in solution within the polymer or dispersed within it. Where the control release substance is dissolved within a rubbery matrix extraction of the substance is usually due to Fickian diffusion of the solute to the surface where the substance is desorbed and enters the water phase. If the matrix material is water swellable, such swelling enhances extraction by increasing free volume and molecular mobility. Release rate characteristics for dissovled substance monolithic systems generally obey $t^{1/2}$ kinetics until about 60% of the substance is released after which the rate is exponentially related to time:[17]

$$\frac{dMt}{dt} = k_1 e^{-k_2 t} \qquad (5)$$

where k_1 and k_2 are constants. This type of release is called "first order" and is also observed in reservoir systems in which the solution of active substance is less than saturated.

For dispersed substance monolithic systems, where the soluble and the dispersed component are in equilibrium within the polymer matrix and the concentration of dispersed particles is sufficiently low so they are not interconnected, release is proportional to $t^{1/2}$. This type of release kinetics holds for almost the entire release curve. Where the solubility of the active agent is sufficiently low, and where the concentration is high, a porous network of interconnecting capillaries or pores exists. Release from such systems is not due to diffusion of the active substance through the polymer matrix but through the elution media.[22] These systems also follow $t^{1/2}$ kinetics. The release rate is directly proportional to the porosity ε and the tortuosity τ of the matrix such that

$$Q_t = [SD \frac{\varepsilon}{\tau} (2A-\varepsilon \cdot S)t]^{1/2} \qquad (6)$$

where Q_t is the amount extracted at time t per unit surface area, S and D are solubility and diffusion coefficients and A is the total concentration of dispersed agent within the polymer matrix.

The Effect of Surface Area

The release of active substance is related not only to the type of system employed but also to the geometry of the controlled release device. Many shapes and sizes are available ranging from large slabs or sheets to microcapsules measured in microns. It is intuitively obvious that given a fixed total volume of material, the release rate will be greater where the surface to volume ratio is large. The release kinetics will be profoundly affected by geometry where the active surface area from which diffusion occurs changes with time due to extraction of material from the outer layers. Certain shapes such as spheres and cylinders favor rapid extraction rates at early times and lower rates later as the effective surface area decreases.[22]

One way to counter diminishing extraction rates with time is to design novel geometries in which the effective area of release increases rather than decreases as a function of time. A right cylinder for example has surface area of:

$$A = 2\pi r(h+r) \qquad (7)$$

If h becomes sufficiently large or r sufficiently small, the area of the end becomes insignificant and

$$A \cong 2\pi rh. \qquad (8)$$

The effective release area as successive shells of SLS are depleted becomes:

$$A_{eff} \cong 2\pi h(r-\tau) \qquad (9)$$

where τ is the thickness of the depleted shell and

$$\frac{\partial A_{eff}}{\partial t} \cong -2\pi h \frac{\partial \tau}{\partial t} \qquad (10)$$

which gives a decreasing area with time. Now consider a hollow tube in which release is through the interior surface into the lumen of the tube. This can be accomplished by coating the outer surface with an impermeable barrier (see Figure 3). The initial area from which release occurs now becomes:

$$A \cong 2\pi r_1 h \qquad (11)$$

where h is large compared to the radius and r_1 is the radius of the lumen. As active agent is depleted from the matrix in shells of thickness τ,

$$A_{eff} \cong 2\pi h\ (r_1+\tau) \qquad (12)$$

Figure 3. a. Tubular shaped release device. Release is through the interior surface into the lumen. The impermeable coating prevents release from cylinder exterior. b. Comparison of release characteristics for tubular device compared to a solid cylinder.

and

$$\frac{\partial A_{eff}}{\partial t} \cong 2\pi h \frac{\partial r}{\partial t} \qquad (13)$$

which gives an increasing area with time. The system can be designed to therefore offset the effect of depletion of the active agent. This concept has already been used by Langer[23] to design hemispherical release devices in which the increase in area exactly offsets the increasing diffusion distance and linear release is obtained over the entire lifetime.

Controlled Release of Sodium Lauryl Sulfate

For acid mine drainage treatment, we have so far tested monolithic polymer systems in right circular cylindrical form. The development and testing of these controlled release devices is described below.

Materials and Methods

All polymer sodium lauryl sulfate (SLS) compounds were prepared either using a standard rubber mill or a Banbury rubber mixer using standard rubber processing industry practice. Cylindrical pellets 1/4 inch in diameter by 1/2 inch high were prepared using a Haake Rheleox 530 extruder to give a smooth uniform output which was subsequently chopped.

The US Bureau of Mines[15] has developed an extraction test which can be used to evaluate the release characteristics of SLS from a polymer matrix under simulated field conditions and have presented release data on SLS rubber systems. The test is time consuming and therefore inconvenient for screening materials. To rapidly screen materials for relative release characteristics a quick extraction procedure was developed.

Fourteen cylindrical controlled release pellets of nominal dimensions 1/4 inch dia. x 1/2 inch and having a surface to volume ratio S/V = 20.0 in^{-1} were placed into a wide mouth quart jar. This number was chosen because it gave a total amount of available SLS for extraction that is easily detectable by X-ray fluorescence analysis for sulfur. A large volume of water was added to the container such that the extractable SLS within the pellets was removed rapidly.

Since total surface area is important the same pellet size and shape were maintained for all tests in which polymer/SLS systems were being evaluated.

Time zero was taken to be the time at which the water was first added to the jars. Five ml of the aqueous phase were removed at 5, 10, 20, 60, 300 and 1440 minutes (24 hours). The containers were constantly agitated except during sampling. Each five ml sample was analyzed for sulfur and the amount of SLS extracted from the pellets calculated.

Results and Discussion

Uncrosslinked natural rubber was found to be an ideal polymer for uptake of SLS. The solubility of SLS in natural rubber was determined to be extremely high using electron microscopy. Further evidence that the SLS was highly soluble in uncured natural rubber was the high modulus of the material due apparently to strain crystallization of the SLS molecules. The release characteristics of numerous rubber compounds are now in the process of investigation to develop formulation

Figure 4. Electron micrographs showing partial cross-sections of a partially extracted 1/4" dia. polyethylene pellet containing SLS. a. View showing extracted zone (top), active leaching zone and an unextracted zone (40X). b. Enlargement of extracted zone showing depleted porous network (500X). c. Active extraction zone showing recrystallized SLS (500X). d. Interior region of pellet containing unextracted SLS (500X).

with more favorable release characteristics. Original formulations were found to be effective for approximately one year.[15] Rubber modifications currently under investigation include higher loadings of SLS, addition of additives to modulate release characteristics and the investigation of crosslinking. Crosslinked systems like uncrosslinked systems accept very high SLS loadings but have different release characteristics due to restricted molecular segment mobility of the polymer cage network.

In addition to natural rubber, thermoplastic matrix materials such as polyethylene (PE) and Ethylene Vinyl Acetate (EVA) were investigated as carriers for SLS. Unlike natural rubber SLS does not appear to be highly soluble in these materials, nevertheless, high loadings were possible. Fickian diffusion through PE and EVA is very slow, due in part to crystalline domains within the polymer matrix. Such domains will not uptake solutions nor allow their passage. Therefore, release of SLS from such a matrix is due to the porous nature of the system. Figure 4 shows cross-sectional electron micrograph views of a partially extracted PE pellet which was freeze fractured to reveal the interior of the pellet. Three distinct zones were observed as revealed in Figure 4a. The edge of the pellet seen in the righthand region of Figure 4a contained a porous network depleted of SLS as shown enlarged in Figure 4b. An intermediate zone (the light colored region in the center of 4a) represents the active front from which SLS was being extracted and contained highly visible recrystallized SLS (Figure 4c) due to removal of the pellet from the extraction medium. The interior portion of the pellet seen at the left on Figures 4a and 4d contained unextracted SLS within the porous matrix. The active extraction front moves progressively from the surface to the interior of the pellet. In such a system both loading level and particle size of the active substance are important determinants in release characteristics of the system.

Figure 5 shows extraction data for three systems. The natural rubber system was similar to previously field tested materials[15] but with more than twice the initial SLS loading. These pellets were completely extracted in less than one day when totally immersed. The polyethylene and EVA systems exhibited much slower release characteristics.

Figure 5. Extraction data for three SLS containing monolithic systems. A. Low density polyethylene. B. Ethylene vinyl acetate. C. Uncured natural rubber.

Effect of Shape, Size, and Other Factors

As discussed in the section on "The Effect of Surface Area", particle size and shape play an important role in governing the effective release rate from pellets. For the purpose of the tests and developments reported here, we chose the right cylinder as the geometry because (1) it was simple to manufacture, (2) the release rate could be readily tailored by changing height or radius, and (3) the pellets could be easily applied in reclamation.

For cylinders in which r>>h, the ends dominate the total surface area and surface to volume ratios are large, while in the case in which h>>r the walls dominate the area and S/V ratios are smaller at equivalent volume. Thus for a cylinder of large r release through the ends is favored while for a cylinder of small r, release through the walls is dominant. Reducing particle size favors rapid extraction as S/V increases rapidly as particle size approaches zero. One additional point should be made. When particle volume is very small, small changes in particle volume result in major changes in S/V. At large particle volume very large volume changes are required to observe significant S/V changes. Thus, if slow release is desired, there is a practical limit of volume beyond which little is to be gained by additional increases in size.

Many factors influence the extraction of SLS from a controlled release system under natural conditions. These include the nature of the controlled release systems, climatological variables, hydrologic factors and the chemical/biochemical environment in which the system exists. Precipitation is probably the dominant climatological factor which effects the rate of SLS release. Rainfall extremes may be as significant as average annual rainfall. Certainly the form of precipitation, be it rainfall or snow, is important as is the state of the ground. Frozen ground is less permeable then non-frozen ground resulting in increased runoff. Snowmelt can saturate the ground and enhance pellet extraction. Refuse piles tend to be less permeable than spoil which effects the percolation rate. Slope and contour elevation relative to the groundwater table are also important parameters in regulating release rates. Pellets which lie in a wet depression will be depleted more rapidly than pellets in a less saturated environment.

Field Demonstration Projects

We are beginning an extensive program of field testing in an effort to better understand

how these variables interact to effect SLS release and to demonstrate the effectiveness of controlled release sodium lauryl sulfate. Two trials are scheduled to begin in the summer of 1983.

The first of these is a demonstration project in conjunction with the Ohio Department of Natural Resources on a site near Wintersville, Ohio in Jefferson County. The site is approximately a 3.5 acre refuse area which will be divided into two tracts. One of the two tracts is to be treated with both spray sodium lauryl sulfate and controlled release pellets while the other tract will serve as a control. Some regrading of the site will be required to provide positive drainage and reduce excessive slopes.

Immediately following controlled release pellet application to the treated tract, both tracts will be reclaimed by applying topsoil and establishing a cover of grass. In order to monitor the sites, lysimeters will be installed in both tracts as will a groundwater drainage collection system near the toe of the slope in each tract.

A second field demonstration project is being conducted in conjunction with the Pennsylvania Department of Environmental Resources at a site in Indiana County, Pennsylvania. The site consists of a refuse pile approximately five acres in size and 10-15 feet in height. The pile is relatively flat and will require minimal grading to insure positive drainage. The pile also contains actively flowing acidic seeps. Unlike the Ohio site this site will not be reclaimed, nor will a control tract be employed. The pile will be treated in the summer of 1983 with both solution SLS and controlled release SLS pellets which will be disked into the surface. Monitoring will be through active seeps and lysimeters which will be strategically located throughout the pile.

These trials will provide large natural laboratories to study not only the effect of SLS on acid generation but on the controlled release process itself. Monitoring will include the traditional water quality parameters such as pH, acidity, alkalinity, total and ferrous iron, manganese, sulfate, conductivity and Eh as well as biological parameters and the fate of SLS and the pellets in the refuse environment. Controlled release pellets will periodically be removed and analyzed for SLS content and evidence of biodegradation. Groundwater will be analzyed for sodium lauryl sulfate content to insure that an effective dosage is being administered and to demonstrate that SLS is not contaminating the environment. This information should provide a far more detailed picture of the controlled release process which will be used in the design of more advanced controlled release systems to eliminate or reduce acid mine drainage.

Bureau of Mines
Technology Transfer

Seminar on
Acid Mine Drainage Control

Bureau of Mines
Technology Transfer
Seminar on Acid
Mine Drainage Control

April 3-4, 1985
Pittsburgh, PA

A special one and a half day meeting updating new research breakthroughs in controlling acid mine drainage from coal mines has been planned by the Bureau of Mines. This seminar will feature technical discussions describing test results in areas such as the prediction of acid mine drainage before mining; how hydrology affects acid mine drainage; the use of alkaline materials for controlling acid mine drainage; and in-line aeration and treatment of acid mine drainage.

Technical personnel will be available at this meeting to answer any questions, and literature packages filled with additional information will be available to the attendees.

A field trip to demonstrate the in-line aeration and treatment system in operation at a local mine has been arranged for interested persons after the seminar. Transportation will be provided between the meeting site and the mine.

Please take a moment to read over the agenda, and if you would like to attend this seminar, simply fill out the attached reply card and return it to the Bureau of Mines at your earliest convenience or give us a call and we will register you over the telephone. If you have any questions or would like further details about this meeting, please contact:

Sheri L. Harris
Branch of Technology Transfer
2401 E Street, NW, MS 1041
Washington, DC 20241
Telephone: (202) 634-1224

Agenda

Wednesday, April 3

9:05- 9:15 a.m. **Introduction and Welcome** by *John Murphy*, Research Director, Pittsburgh Research Center, Bureau of Mines

9:15- 9:35 a.m. **Technical Overview** by *Robert Kleinman*, Pittsburgh Research Center

9:35-10:40 a.m. **Pre-mine Prediction of Acid Mine Drainage:**
- **Field evaluation of current technology** by *Patricia Erickson*, Pittsburgh Research Center and *Andrew Sobek*, Engineers International
- **Pyrite reactivity and relationship to thermal activity** by *Richard Hammack*, Pittsburgh Research Center

10:40-11:00 a.m. **BREAK**

11:00-11:45 a.m. **Hydrological Aspects of Acid Mine Drainage Control** by *Kenneth Ladwig*, Pittsburgh Research Center

11:45 a.m.-1:00 p.m. **LUNCH**

1:00- 1:20 p.m. **Gas composition of Coal Spoil and Refuse** by *Patricia Erickson*, Pittsburgh Research Center

1:20- 2:20 p.m. **Bactericidal Control of Acid Mine Drainage:**
- **Review of previous work with anionic surfactants** by *Robert Kleinmann* and *Patricia Erickson*, Pittsburgh Research Center
- **Use of alternative materials such as benzoate and sorbate** by *Robert Kleinmann*, Pittsburgh Research Center
- **Slow release by bactericidal agents** by *Vijal Rastogi*, B. F. Goodrich

2:20- 2:40 p.m. **BREAK**

2:40- 3:30 p.m. **Injection of Alkaline Materials for Control of Acid Mine Drainage** by *Kenneth Ladwig*, Pittsburgh Research Center

3:30- 4:10 p.m. **Alternative Methods to Remove Manganese from Acid Mine Drainage** by *George Watzlaf*, Pittsburgh

Questions, Answers and Discussion

Use of Sphagnum Moss/Limestone for Treatment of Acid Mine Drainage by *Robert Kleinmann*, Pittsburgh Research Center, *Brent Huntsman*, Wright State University, and *Benjamin Pesavento*, Environment Analytic

BREAK

In-Line Aeration and Treatment of Acid Mine Drainage by *Terry Ackman*, Pittsburgh Research Center

Questions, Answers, Discussion

Closing Remarks by *Robert Kleinmann*, Pittsburgh Research Center

LUNCH

Optional field trip to see in-line system in operation at a local mine led by *Terry Ackman*, Pittsburgh Research Center

Technology Transfer Group
Bureau of Mines
2401 E Street, N.W.
Washington, D.C. 20241

In South Africa, methods for the inhibition of acid mine drainage using different chemicals along similar lines is a topic of research at the University of Stellenbosch. This is a joint project between the Institute for Polymer Science and the Dept. of Microbiology, funded by the South African Water Research Commission. Confidentiality seems to be one of the stipulations of Water Research Commission research, but whatever information can be released could be requested from:

4. Low Grade Phosphate Rock Addition - Experimental Process

Dr. Al Stiller has demonstrated a remarkable application of basic chemistry which offers a potential solution to AMD from finely disseminated tailings containing oxidizable sulfides such as, for example, coal flotation refuse and base metal sulfide flotation tailings.

Examining the sequence of reactions that result in AMD generation, it becomes clear that two initial reactions pay a role: 1) bacterial oxidation of ferrous ions to ferric ions; 2) reaction between ferric ions with pyrite and other sulfide minerals as shown in equation 4. The second reaction causes by far the greatest generation of acid.

$$2FeS_2 + 7O_2 + 2H_2O = 2Fe^{2+} + 4SO_4^{=} + 4H^+ \quad (1)$$

$$4Fe^{2+} + 10H_2O + O_2 = [4Fe(OH)_3]^{+5} + 2H^+ \quad (2)$$

$$4Fe^{2+} + O_2 + 4H^+ = 4Fe^{3+} + 2H_2O \quad (3)$$

$$FeS_2 + 14Fe^{3+} + 8H_2O = 15Fe^{2+} + 2SO_4^{2-} + 16H^+ \quad (4)$$

By adding an intimate mixture of low grade phosphate rock with the tailings, the AMD generation can be inhibited by the following surface reactions.

$$3H_2SO_4 + Ca_3(PO_4)_2 = 3CaSO_4 + 2H_3PO_4$$

$$H_3PO_4 + 3OH^- = PO_4^{3-} + 2OH^-$$

$$3Fe^{2+} + 2PO_4^{=} = \underline{Fe_3(PO_4)_2}$$

$$Fe^{3+} + PO_4^{=} = \underline{FePO_4}$$

Ferrous phosphate has a solubility coefficient of 10^{-22}, and ferric phosphate is also almost insoluble.

At very low pH levels around pH 3.0-3.25, phosphate rock dissolves readily. In an oxidizing tailings pile, the pH of seepage may be around 2-5, but at the actual oxidation site on the mineral surface where reaction is occurring, the localized pH is about pH 1. Consequently, if phosphate rock can be brought in close contact with the tailings particle, the phosrock will be locally dissolved where needed. When this happens, ferrous and ferric phosphate immediately coat the particles and inhibit further reaction. It is claimed that acid generating bacteria that normally play such an important role in AMD generation are unable to oxidize ferrous ions once they have been precipitated in this way so the energy source vital to their growth is made unavailable.

This method for inhibition of AMD has been demonstrated on bench scale and also in barrel quantities. It is now being demonstrated on 350 ton test piles at:

ENOXY COAL, INC.
Post Office Box 710
Buckhannon, WV 26201
(304) 472-9272
Allan Meek

The development and testwork is being funded by the West Virginia Dept. of Natural Resources.

Tests have indicated that low grade phosphate rock slimes, an environmental disposal problem in Florida, are suitable for use. The schmectite clay content of the slimes is also useful for its soilmaking properties for the restoration of the tailings, however, these slimes are very bulky and may not justify the cost of shipment.

Importantly, the amount of phosphate rock needed is not stoichiometric because this is a surface reaction, and it is therefore not necessary to react the full mass of iron sulfides. Phosphate rock slimes are available delivered to Morgantown, West Virginia, at a cost of $50/t.

This innovative emerging technology deserves attention and support for more testwork and development. It is particularly appropriate where tailings are disposed of in slurry form, and the finely divided phosphate rock can be readily added and mixed into the pulp without great cost. If it proves practicable for commercial use, then it may lend itself to mixing with a high pyrite fraction that can be separated from base metal tailings to yield a more easily disposable low sulfide tailing and a smaller volume of high sulfide tailings to be mixed with the phosrock for disposal in a way that inhibits AMD generation.

More information on the concept and progress to date is available from:

DR. AL STILLER
Dept. of Chemical Engineering
University of West Virginia
Morgantown, WV
(304) 293-5398

An immediate offshoot from this concept would be the possibility of applying phosphate in liquid form to wasterock and tailings; however, here the risk of complicating the issue through phosphate pollution effects and the possibility of introducing phosphate in such a way that bacterial growth would be enhanced rather than inhibited must be considered.

5. Burnside Colliery, Glencoe, Natal

Gencor Ltd. spent a considerable amount of money and effort to restore the old worked out Burnside Colliery at Glencoe, Natal, South Africa. Several physical methods have been employed with remarkable success to control and inhibit acid mine drainage from the old minesite including old waste piles that were active. Whether or not these measures would be adequate to meet all requirements of a U.S. permit, which requires groundwater protection to be taken into account, is debatable. The measures, however, certainly made a big impact on the aesthetics of the site and the usability of the land and local streamwater. These measures were:

- Diversion of a drainage stream around the coal waste dump that had been located on the stream channel.

- Construction of a 80,000 m^3 capacity dam to collect and retain runoff water above the waste pile. Water is released at a controlled uniform rate so as not to erode the dump. Cost - R100,000.
- The coal waste dump was recontoured so precipitation will drain off the dump with no standing pools and a minimum of seepage into the dump.

- The coal waste dump surface was compacted to further reduce air and water penetration.

- The sides and top of the dump were planted with Kikuyu grass. Normal Kikuyu grass died, but grass taken from the immediate vicinity was acclimated to the lower pH and survived well.

- Collection dams were constructed to retain any surface drainages from the waste dump for evaporation.

- The shaft opening was sealed by a 2 m thick concrete plug and provided with a collar to prevent water from draining into the shaft. A valved pipeline was embedded through the plug to allow excess water to be bled at times when the

nearby river is in flood during which time released water would drain to the sea without causing damage.

The results of the R3 million site restoration program are highly successful. Water flowing into the nearby creek now meets effluent limits, and the creek water is once again usable for livestock watering and crop irrigation.

Clearly, coal mine waste reclamation in South Africa is possible without necessarily resorting to chemical AMD inhibition. Gencor Ltd. kept the manager of the mine at the site for three years after its closure to supervise the restoration program. This manager at first may have resented the task; however, he is now in charge of developing the latest Gencor Colliery where he can apply his restoration experience to the design and layout of the new operation. This is certainly an astute and innovative management move, considering the extent to which restoration costs can be reduced if properly planned in advance.

More information can be requested from the man responsible for the program:

6. Kromdraai Coal Mine

The Old Coronation Coal Mining Division of the Kromdraai Coal Mine is located near Witbank in the Transvaal, and belongs to the Anglo American Corporation. This site has been beautifully restored to the extent that, apart from the water treatment plant, there are now virtually no signs of the old mining operation.

When the mine was closed down in 1970 and the site restored, a flow of acid mine drainage amounting to 14,000 m^3/d with 1750 mg/l TDS and pH 2.2-2.4 had to be treated for discharge. The initial lime neutralization plant resulted in a sludge volume equal to 10% of the original flow, and it was possible to achieve a 4% solids density. The prospect of having to dispose of an estimated 1,400 m^3/d of sludge required a costly surface impoundment. This led to the highly successful installation of a high density sludge process plant yielding a sludge with a density of about 30-34% solids and which could have been increased had there been a need to do so.

Initially, the plant operated at 14,000 m^3/d working 24 hours/day, but after three years, the mine was successfully dewatered and today the plant is operated only eight hours per week.

At the full rate of operation, lime consumption amounted to R0.05/m^3 treated at a lime cost of R18-R20/t.

The high density sludge is disposed of to a surface impoundment where it soon dries to a low density dry material that is stable enough to be walked on.

Apart from the fine performance of the Kromdraai HDS plant which is described in Appendix I, the main point in referring to it here is that, were it known that the flow into the mine would decline, a smaller plant could have been designed. The Kromdraai HDS plant was one of the first HDS installations in the world. Since the owners had no prior experience in the HDS plant performance at that time, they may have felt it was necessary to overdesign the plant to be on the safe side. The Kromdraai experience has led to identification of the benefits of finding ways to prevent water from getting into a mine as a way of reducing the need for AMD treatment.

By installing an oversize plant, it was also possible to dewater the mine faster, thereby reducing the rate at which acid is generated underground and cutting back on the overall lime consumption, which would be an example of adopting a systems approach. This method of reducing AMD generation is described by WATSON (1982).

More information on the Kromdraai HDS plant could be obtained from:

ANGLO AMERICAN RESEARCH
LABORATORIES
Post Office Box 106
Crown Mines 2025
(011) 835-3251
Danie J. Bosman

It has also been described by BOSMAN (1974).

7. Rapid Dewatering of Coal Seams

WATSON (1982) and BOSMAN (1982) report that significant reductions in the rate of acid formation have been obtained where it is possible to prevent water collecting in underground pools in mines.

6. AMD Abatement by Discouraging Oxidation

The chemical requirements for unrestricted oxidation of iron sulfide minerals include an adequate supply of water, oxygen, carbon dioxide, ammonia, phosphorous, and various micronutrients. The restriction or elimination of the supply of one of these will influence acid generation. In the extreme case, the process can be completely inhibited by providing a hostile environment for the bacteria. It is not considered feasible to inhibit the oxidation process by the conscious control of micronutrients as these are

generally available in the water. However, considerable effort has been directed toward the conscious creation of a hostile environment for the bacteria with the objective of eliminating or substantially reducing the problem at the source.

These have included:

- Restricting the supply of oxygen.
- Restricting the supply of water.
- Isolating the sulfide components.
- Reducing the ferric iron levels.
- Controlling pH.
- Use of bactericides.
- Limiting the area of reactive surfaces.
- Controlling temperature.

Restricting the Supply of Oxygen

Oxygen enters a mine or tailings area both as a gas phase and as a dissolved component in the water. Water can supply only a limited amount of oxygen since 8-9 ppm of oxygen in water is the saturation level which corresponds to a maximum of 15 ppm acid according to equation 1.

Oxygen in an operating mine cannot be restricted on a practical basis at this time. Experiments performed in the USA, using an inert mine atmosphere and providing the work force with a separate life support system not surprisingly did not prove practical.

After abandonment, seals can be used to restrict both oxygen and water entry, and this approach as been used successfully in some old coal mines in the U.S.A. The sealing of surfaces of open pit mines is still not fully developed, and those pits which generate acid are a major unsolved problem in the future development of control technology.

Restricting oxygen access to stored tailings and sulfidic wastes has a greater chance of being viable. Techniques available for control of long term acid seepage from waste embankments are:

(i) Revegetation

An active soil layer consumes oxygen in its uppermost layers and may gradually become anaerobic if enough organic soil is available. The addition of sewage sludge or other decaying organic matter not only helps consume oxygen but also aids in the rapid establishment of a self-sustaining soil cover.

This approach is site specific. For example, on the Witwatersrand it was found that established grass vegetation on the dumps failed to prevent oxidation of tailings although it prevented windblown distribution of sulfide-bearing silica tailings to the environment.

More information on the oxidation within Witwatersrand gold and uranium mill tailings and the effect of grass cover can be requested from the Chamber of Mines of South Africa, although requests on behalf of this investigation were not very rewarding.

MR. D. MARSDEN
Chamber of Mines of South Africa
No. 4 Shaft, City Deep Mine
Alberton, Transvaal
South Africa
(011) 86-7358

Climatic constraints may have something to do with the failure of grass cover to prevent pyrite oxidation in Witwatersrand tailings in that during winter the grass effectively dies, and there may not be adequate organic humus generated to yield the anaerobic soils. Also, air may penetrate from the base or sides of the dumps. Appalachia has an ideal climate for dense vegetation and seasonal variations, such that most of the vegetation is deciduous so generation of anaerobic soil layers may possibly be more effective.

Revegetation - Canada

The high pyrite-pyrrhotite tailings observed at several operations including Noranda's Waite-Amulet and Horne Division in Quebec, Inco and Falconbridge at Sudbury and Onaping, Ontario, and the major uranium mill tailings near Elliot Lake supported vegetation in a widely varying degree ranging form negligible to lush. At Waite-Amulet, a way was developed to grow a prolific stand of birdsfoot trefoil (a legume) and creeping red fescue (a grass) directly in a limestone pH modified pyritic tailings surface. Several stands of spruce have also volunteered on the tailings. Noranda Mines Ltd., in conjunction with consultants at the University of Guelph, have developed a bio-assay method to select viable species and appropriate conditions for planting.

More information on the prominant success in revegetating the Waite-Amulet tailings can be obtained from:

NORANDA MINES LTD.

The question now remains as to whether the vegetation method developed is successful in inhibiting AMD generation as well as preventing windblown distribution of AMD-generating dust to a wider area and looking good.

On several pyrite-rich tailings observed at Elliot Lake, the oxidized cap supports a moss growth which forms a new surface layer every year. There were signs of capillary action transport of salts to the surface with evaporites forming at the surface. As shrinkage cracks develop in the mass surface, spruce seedlings were germinating and growing. Some small trees had taken hold, but their root system was limited to the moss layer which did not appear able to support mature trees. A capillary barrier would undoubtably have helped provided there is enough soil covering it to store moisture to support the vegetation.

At Falconbridge's Onaping operations in Ontario, experiments are being undertaken to place a layer of crushed wasterock and municipal garbage over the segregated high sulfide tailings to act as a capillary barrier. Then the layer is sprayed with sewage sludge, and finally, it is planned to place a layer of sterile low sulfide tailings over the top which can be fertilized and seeded. The program is in a developement stage and at the time of the RANDOL summer of 1984 visit, there was not much vegetation to observe, but the results of these experiments will be very well worth following as they develop.

More information about this innovative systems approach can be obtained from:

INCO Ltd. has 2700 acres of disposal area at one site alone which is fertilized and seeded with rye and harvested annually. This seems expensive and less attractive from a long-term restoration point of view for abandonment than Noranda's vegetation program using birdsfoot trefoil which is adaptable, winter hardy and maintenance-free once established. On the other hand, in some parts of the world, perhaps tailings could support an ongoing profitable agricultural industry.

SOURCES OF ACID MINE DRAINAGE

CAPILLARY AND RUNOFF TRANSPORT OF SALTS FROM HIGH-SULPHUR TAILINGS

CONCENTRATE SPILLS AROUND TRACKS AND CAR LOADING AND OFFLOADING AREAS

WASTEROCK COVER OVER HIGH SULFUR TAILINGS
FALCONBRIDGE ONAPING OPERATIONS

(ii) Flooding

Water is an excellent diffusion barrier for oxygen. The depth of water needed in a given case is a function of the size of the pond and the wave or mixing action taking place. This technique does, however, require an impervious embankment. It is also not applicable as long-term control in areas where evaporation exceeds precipitation.

(iii) Sealants

Chemical sealants have been used with some success. Typically an aqueous solution of the sealant is sprayed onto the surface of the tailings which, when cured, forms a semi-flexible impermeable mat. The sealant is often mixed with fibrous material to improve its strength and binding properties. Unfortunately, the sealant has a finite life and must be renewed generally every two to three years.

On certain high sulfide tailings with up to 90% pyrite and pyrrhotite, as observed at several mine-mill complexes in Canada, the sulfides formed their own almost impermeable skin on the surface exposed to the air. At Waite-Amulet, for example, a two to three foot layer of the iron sulfide-rich tailings pile was oxidized to yield a strong cemented crust. Below that, the sulfide concentrate was still grey (unoxidized) in color and had a soupy consistency. In this case the pile had formed its own sealant shell. It was strong enough to support a pickup truck, but not for heavy equipment operation on top of these ponds.

At Noranda's Waite-Amulet tailings, prior to their very successful revegetation program, the surface would occasionally dry out to yield undesirable dust problems resembling dust storms. Chemical sealants suffered wind damage, and after 2-3 years, 25-30% of the sealant had blown away according to informal information provided by employees.

Cotter Corporation's old millsite is a cause of acid drainage contamination of groundwater due to leaching from an unlined former ore storage area. This may be overcome by placing an impermeable clay capping over the area to prevent water from reaching the source of contaminants. A similar effect, although expensive, may prove useful in preventing AMD from generating in sulfidic tailings or waste impoundments when the site has to be restored.

9. Wasterock Utilization

Another important way to inhibit AMD is through careful use of wasterock. Many mines in Ontario, Quebec, and elsewhere use wasterock to build road and railbeds, as fill for storage areas and workshop yards, as tailings dam walls, or inside and outside riprap. One mine in Ontario discharges neutralized decant water containing 0.9 ppm Ni, and by the time it reaches the receiving waters and discharge sampling point, the level has increased to 1.0 ppm Ni in the course of about half a mile of stream alongside the road.

The roadbed was built of wasterock, and AMD from this small stretch of road is enough to contribute 10% to the nickel value in the final effluent.

Very careful use of wasterock both above ground and underground is required to control AMD.

Many Canadian massive sulfide orebodies lend themselves to cut and fill mining techniques. Wasterock is crushed and used as backfill underground where it is mixed with coarse sand from the tailings and cement. It is usually found that cement addition inhibits AMD generation underground from the backfill material.

In some cases where tailings and wasterock are very high in pyrrhotite, they cannot be used as backfill because they can be so reactive as to catch fire. This material is usually disposed of in the tailings pond or wasterock pile where it is a likely acid generator.

10. Concentrate Stockpiles and Transportation

Concentrate left in the open will also generate AMD in surface runoff and seepages. Careless handling of concentrate stockpiles and spillages must be avoided for this reason. These are likely to occur in areas where concentrate is loaded and unloaded onto trucks and railcars and along roadways and rail lines along which concentrate is hauled. Railcars and trucks must be kept in good repair to prevent leaks of material.

At Falconbridge Onaping works, the surface of a railcar loading site was ripped up and processed through the mill to prevent AMD contamination of a potable water well. Undoubtedly this also occurs at other millsites. Outdoor handling and open stockpiles of concentrate can also result in windblown distribution of concentrate which can result in AMD too.

11. Backfill of Tailings and Wasterock

Sulfide-rich wasterock and tailings can be disposed of as cemented backfill as a means of inhibiting acid mine drainage. This serves two purposes. First, the material once stored underground in this way is much less likely to generate AMD that can impact the environment. First the material is encapsulated and mixed with cement which has a high pH and, therefore, inhibits oxidation of sulfides. Second, by filling the stopes underground, there is less room for water to accumulate or to circulate and, therefore, two sources of AMD are inhibited at the same time.

There are limitations, however. 1) Not all the mined tailings and wasterock will fit into the cavity because of the expansion factor when it was crushed. At least 40% will have to be disposed of elsewhere. 2) Some of the material that is richest in sulfides from

massive sulfide mines cannot be used as backfill because it is pyrophoric and may generate heat or even catch fire underground. 3) Once tailings and waste has been disposed of in this way, it is not that easy to reclaim them if, at a future date, they would represent valuable resources had they been stored on the surface.

12. Deep Lake and Submarine Disposal of Tailings

The disposal of tailings in deep lakes may represent one of the best disposal alternatives from the AMD point of view where such lakes exist, and this is done in several cases. The full ramifications of the effects of deep lake disposal need to be considered, however.

In shallow lake tailings disposal, wind and wave action may regenerate the oxygen supply, and some degree of oxidation may be experienced. Here, the idea of KALIN (1984, personal communication) of establishing an underwater plant cover which would serve to generate an anaerobic zone on the water-tailings interface and simultaneously also potentially remove some undesirable dissolved metals and suspended solids from the water above.

HAWLEY (1975) cited the following advantages of underwater (deep) tailings disposal:

(1) Low operating and maintenance costs.

(2) Large capacity.

(3) Tailings deposits in deep water sites are not in direct contact with the atmosphere. It is logical to assume, therefore, that chemical reactions at land tailings sites such as between reactive tailings particles such as iron sulfides and atmospheric oxygen, etc., are either subdued or absent in many deepwater sites. To be more specific, it is extremely probable that acid generation problems due to the reactions involving sulfide gangue minerals in situ in tailings masses would be completely or largely eliminated by using proper deepwater tailings disposal procedures (in either salt water, which would be preferable because of its alkaline nature, or in fresh water).

(4) Less chance of mechanical failure.

(5) On completion of the project, the deepwater disposal site can be completely hidden with no revegetation needs.

The disadvantages cited were:

(1) No opportunity to recover a decanted solution.

(2) Migration of fine particles of solids which can't be confirmed underwater.

(3) Underwater disposal may have a large number of direct impacts on fishery resources.

(4) No chance to control environmental impacts that develop after the fact.

(5) Not nearly enough is known about the effects of this practice on the environment.

Despite the potential advantages of deep lake disposal of tailings for several Canadian operations, including the uranium operations at Elliot Lake, this practice is not currently employed on the Canadian Shield. The reasons are not clear.

There have been cases where settling ponds have been used to trap concentrate particles from water runoff draining from base metal mills. Many years later these ponds were dredged and found to yield a sulfide concentrate that could be used either as an incremental metal source in the smelter (as at Falconbridge, Ontario), or as feed to the flotation circuit (as at St. Joe, Balmat, New York). In the case of the ponds at Falconbridge, although the concentrate could be recovered, the quality of the water in contact with it in the shallow pond had a high metal content which had to be precipitated prior to discharge. The significance of this is that shallow water impoundments of sulfide wastes will not solve the problem.

HAWLEY (1975) referred to the fact that, in mountainous terrain near the sea, several mining companies use the sea as a tailings disposal area, e.g.:

Bouganville Copper,	78,000 tpd
Utah Mines Ltd., Vancouver Island	15,000 tpd
Atlas Consolidated, Cebu, Phillipines	63,000 tpd
Greenex Mines Ltd. (Cominco), Greenland	

Deep water lake disposal of sulfide tailings is already practiced by Western Mines Ltd. at their Myra Falls copper-zinc flotation plant in British Columbia which could be a good site at which to test the degree of oxidation of the sulfides and the effect on water in contact with the tailings.

AMD Inhibition - Systems Approach and Summary

In order to inhibit AMD, a systems approach can be a big help even though the final answers as to the best way to completely prevent it are not yet known.

In open pit mines, to date, there do not seem to be any answers other than to keep water out of the pit and to cut off seepages and drainage into the pit. COMINCO solved the acid mine drainage problem at their Wedge Mine in New Brunswick by filling the pit back up again with wasterock and revegetating the site after sealing and contouring the surface.

In underground mines, it appears that AMD can be reduced by sealing the mine, keeping the mine dry, and possibly by using volatile bacteria inhibiting chemicals to penetrate the fractures.

With selective use of wasterock above ground and appropriate disposal of wasterock and tailings in such a manner, AMD is minimized. Where AMD generation is unavoidable, it can be neutralized by placing potential acid generating wasterock over basic calcerous waste in the impoundment or storage area as has been designed in HOMESTAKE MINING CO.'s new McLaughlin gold operation.

Several disposal methods which incorporate synergistic use of urban garbage and sewage sludges were mentioned above as well as ways to revegetate waste and tailings to reduce oxygen and water incursions.

Good housekeeping of ore and concentrate stockpiles is essential.

In some cases, pyrite is now floated from gold-uranium tailings for use in making sulfuric acid, and this leaves the tailings with a much lower sulfide mineral content. Such tailings have a correspondingly reduced acid generating capacity.

In some more recent uranium extraction developments, pressure oxidation and leaching is employed which consumes the acid generating sulfide in the ore leaving tailings inert and more easily stabilized for disposal.

Where water is to be treated, the capital and operating costs depend on the volume of water to be treated. Therefore, appropriate diversion of runoff from outside the area makes it possible to reduce the effective watershed and hence the volume of water to be treated and thereby also reduce operating and capital costs.

The magnitude of the acid mine drainage problem is so great, and the costs of meeting regulatory requirements for operating and abandoned mine, mill, and tailings sites are so huge, that this area deserves urgent and special attention. A concerted effort is required to fully understand and characterize acid mine drainage and to develop ways to inhibit or prevent it. No effort or expense should be spared in these endeavors.

ACID MINE DRAINGAGE

INTRODUCTION

A very wide range in approach was found in the treatment of AMD. In this discussion, AMD is used in the sense of all water and effluents that have undergone a change in composition through contact with sulfide ore, gangue, wasterock, tailings, etc. Usually, this results in a reduced pH and elevated levels of sulfate, iron, and many metals such as Cu, Zn, Cd, Hg, Su, Ni, Co, Mn, etc. In the context used here, the water may never have been in a mine nor need it be acid--just impacted by a mining activity past or present.

Treatment of AMD ranges from simple addition of lime or limestone for pH adjustment in a passive system to an elaborate sequence of settling, oil removal, pH adjustment for precipitation, coagulation, solid-liquid separation to remove precipitates, clarification, and acid addition for final pH adjustment before discharge. Some of these applications are listed in the table overleaf.

The selection of an appropriate treatment plant depends on many factors including flowrate, composition, topography and the environmental sensitivity and permit regulations for discharge. The treatment methods to choose from include:

1) Lime addition and pond settling.
2) Limestone addition and pond settling.
3) Lime addition, thickener-clarifier, filtration.
4) Lime addition, thickener-clarifier, polishing pond.
5) High density sludge process (HDS).
6) High density sludge process plus desalination.
7) NaOH addition, static mixer, settling pond.
8) NaOH addition, continuous filtration.
9) Limestone passive system, biological polishing pond.
10) Polishing pond alone.
11) Alumina-lime-soda process.
12) Seeded slurry reverse osmosis/evaporation.
13) Low pressure ultrafiltration with charged membranes.

Several of these systems are still in the experimental stages, and although there has already been significant innovation, there is room for much more. Several useful, innovative, and interesting approaches were found during this investigation. Here some of the highlights are discussed.

ACID MINE DRAINAGE TREATMENT

Company	Location	Type of Mine-Mill	Precipitating Reagent	Process	Capacity m^3/d	Effluent Treated	Comments
Bethlehem Mines Corp.	Mine 77, Cambria Division	Bituminous Coal	Lime	HDS	2,195	AMD	Conventional thickener-clarifier.

Water Recovery from Acid Mine Drainage

ROGER C. WILMOTH and ROBERT B. SCOTT
U. S. Environmental Protection Agency, Cincinnati, Ohio

Proc. Third National Conference on Complete Water Re-Use
June 27-30, 1976, Cincinnati, Ohio

Acid mine drainage (AMD) is a major deleterious pollutant associated with the coal extraction industry. The AMD is formed by the oxidation and subsequent hydrolysis of pyrite (FeS_2) yielding sulfuric acid and water. The sulfuric acid, in turn, dissolves metallic and other elements from the surrounding strata or material. An AMD stream with a *p*H below 3 is common in regions where this problem is most intense. Acidities between 20,000 to 30,000 mg/liter as $CaCO_3$ can be found in some seeps from the refuse piles of West Virginia and Pennsylvania and in some strip mine ponds in Illinois.

The problems of AMD are most significant in the eastern coal mining regions where enormous quantities of pyritic shales are exposed during the extensive surface and underground mining operations found there. This is not to imply that AMD is found only in the East; for example, significant AMD pollution is associated with the gold-mining operations in Colorado as well as the lead-silver mines in Montana. In general, AMD is a problem associated with the extraction of all the sulfide-associated minerals (e.g., lead, zinc, copper, etc.) where their occurrence is in nonarid areas. With the increased emphasis on energy and the simultaneous expansion of western mining operations, the problem of AMD must receive increased attention.

The U. S. Environmental Protection Agency (EPA) is currently conducting and/or sponsoring research in the field of AMD treatment. Several of these current projects are sufficiently advanced to report the major conclusions. Seven major treatment processes will be briefly discussed in this report (i.e., limestone neutralization, lime neutralization, combination limestone-lime neutralization, lime-soda treatment, alumina-lime-soda treatment, reverse osmosis treatment, and ion exchange treatment). The emphasis will be placed on effluent quality, operational limitations, cost, and overall applicability.

Neutralization of AMD is accomplished by the addition of an alkaline reagent to elevate the *p*H to a level (generally 7 to 8) where statisfactory precipitation of such metals as iron and aluminum is effected. The trade-off for iron and aluminum removal is an increase in the calcium level where calcium neutralizers are used. Neutralization has very little effect upon total dissolved solids levels.

LIMESTONE NEUTRALIZATION

Considerable energy input and process complexity are involved in transforming (calcining) limestone ($CaCO_3$) into lime [CaO or more commonly

Note: All units are mg/liter except for conductivity (micromhos/cm) and *p*H. Alkalinity and acidity are expressed as $CaCO_3$.

$Ca(OH)_2$]; therefore, limestone is a considerably cheaper reagent than lime.

Unfortunately, limestone does not react efficiently with AMD. The reaction is especially inefficient in AMD situations where the iron is in the ferrous state. Because of this and the fact that it is difficult for limestone to elevate the *p*H beyond 7 (therefore the iron oxidation rate is very slow), the use of limestone is generally considered unfeasible for ferrous iron situations. Chemical cost reductions as great as 30% have been noted in ferric iron situations when limestone has been used as the neutralizing agent in place of lime. An example of the relative effectiveness of limestone in neutralizing ferrous versus ferric iron AMD is presented in Table 1. Chemical analyses of influent and product water from that study are presented in Table 2. Use of coagulants can significantly improve effluent quality but can add as much as $.10/1,000 gal. to the treatment cost. The effectiveness of coagulant addition during limestone

treatment of ferrous AMD is shown in Table 2 Example Two.

The effluent water from limestone (and lime) neutralization processes are typically hard because of the high calcium and magnesium concentrations.

As much as 5% of the influent AMD volume exits as a dense, difficult-to-handle sludge. Adequate sludge disposal technologies are not available.

LIME NEUTRALIZATION

Calcium hydroxide (hydrated lime) is the most frequently used reagent for AMD treatment. Lime is readily available, moderately expensive, highly reactive, and versatile in its application to AMD treatment. It is almost always used for ferrous iron treatment situations because it can readily elevate *p*H to enable rapid iron oxidation.

Typical data for lime neutralization of AMD are presented in Table 3 to illustrate operating parameters. Water analyses are tabulated in Table 2—Example Three for comparison with other treatment techniques. As in the case of limestone, the high calcium and magnesium levels render the water quite hard. Chemical costs during these studies were between $.10 and $.20/1,000 gal. including coagulant costs. Sludge from lime neutralization occupies a much larger volume than limestone sludge but is easier to handle.

COMBINATION LIMESTONE-LIME NEUTRALIZATION

Two-stage treatment composed of first-stage limestone addition to approximately *p*H 6 followed by second-stage lime treatment to *p*H 8 has been shown to offer reagent cost reductions as high as 30% as illustrated in Table 4. No improvements in effluent water quality were obtained (Table 2—Example Four) as compared to lime treatment. Likewise, there is no reduction in TDS from any of the neutralization

Table 4.
Neutralization Data Summaries for Combination Treatment with Reduced First-Stage Limestone Addition (Process A) versus Lime (Process B) Using Coagulants

processes. Sludges from combination treatment are similar to those from lime treatment. Quantification of operating parameters for limestone, lime, and combination treatment were made at the EPA Crown Mine Drainage Control Field Site, Rivesville, West Virginia.

LIME-SODA TREATMENT[1]

This process involves lime neutralization to *p*H 11 for magnesium removal, addition of soda ash (sodium carbonate) to precipitate calcium as calcium carbonate, and final *p*H adjustment to neutrality by the addition of carbon dioxide. The removal of calcium and magnesium significantly decreases the hardness of the effluent. Typical operating parameters are given in Table 5 and chemical data are presented in Table 2—Example Five. These data were generated from an operational full-scale (7 mgd) treatment plant in Altoona, Pennsylvania. The AMD in this situation is extremely dilute. Total treatment costs (including capital, amortization, and operating) were estimated near $.40/1,000 gal. Sludge disposal was not considered in the cost estimates.

In this particular set of data quoted on this process, the effluent quality is almost potable. The influent AMD, however, is unusually mild as previously emphasized, and it is important to note that this process will not normally produce potable-quality water because the TDS levels are not reduced during treatment and the great majority of AMD waters contain greater than 500 mg/liter TDS (the potable limit), including sulfate levels much higher than 250 mg/liter (the potable limit).

Table 5.
Typical Operational Data for Lime-Soda Treatment of Mild-Quality Acid Mine Drainage

	Mean
Flow, mgd	3.5
Flow, cu m/sec	0.15
Lime usage (neutralization), lb./1,000 gal.	1.53
Lime usage (neutralization), kg/cu m	0.18
Soda ash usage (softening), lb./1,000 gal.	2.63
Soda ash usage (softening), kg/cu m	0.32
Carbon dioxide usage (recarbonation), lb./1,000 gal.	0.43
Carbon dioxide usage (recarbonation), kg/cu m	0.05
Chemical cost (neutralization), cents/1,000 gal.	2.68
Chemical cost (softening), cents/1,000 gal.	8.68
Chemical cost (recarbonation), cents/1,000 gal.	1.85
Total chemical cost, cents/1,000 gal.	13.21
Total chemical cost, cents/cu m	3.49

The near-potable capability of the process enables the potential blending of the effluent with insufficient quantities of high-quality water to augment the potable supply. In fact, this is the current use of the 7.0 mgd plant presently operating at Altoona.

ALUMINA-LIME-SODA TREATMENT[2]

A close relative to the lime-soda process, the alumina-lime-soda scheme utilizes the addition of sodium aluminate rather than soda ash. Lime neutralization is taken to *p*H 12 where the sodium aluminate combines with the sulfate and calcium to precipitate as calcium sulfoaluminate. Magnesium precipitates as magnesium hydroxide as in the lime-soda process. In the second stage, carbon dioxide is added to precipitate the excess calcium as calcium carbonate and to reduce *p*H as in the lime-soda process. In contrast to the lime-soda process, the alumina process will reduce the sulfate and TDS levels; therefore, the process will produce a potable effluent.

This process was demonstrated on a bench-scale basis at an AMD source near DuBois, Pennsylvania (Hollywood Treatment Plant). To decrease costs, only 80% of the total AMD was treated by the process and the high-quality effluent was blended with the remaining 20% to degrade the product to the upper limit of potable levels (250 mg/liter of sulfate was the controlling parameter). Typical operating data are given in Table 6 and chemical data are presented in Table 2—Example Six. Chemical costs for the reported study were around $.90/1,000 gal. Some improvement in costs can be obtained as the process is not optimized and bulk prices of sodium aluminate could be reduced by increased demand. Again, no considerations were made of sludge disposal.

Table 6.
Typical Operational Data for Alumina-Lime-Soda Treatment of Acid Mine Drainage

	Mean
Flow, mliter/min	170
Lime usage, lb./1,000 gal.	13.17
Lime usage, kg/cu m	1.58
Sodium aluminate usage, lb./1,000 gal.	4.26

Chemical cost (carbon dioxide), cents/1,000 gal.	6.4
Total chemical cost, cents/1,000 gal.	87.
Total chemical cost, cents/cu m	23.

REVERSE OSMOSIS TREATMENT[3]

Reverse osmosis involves the passage of water molecules from the side of a semipermeable membrane containing a higher concentration of pollutants to the side containing the lesser concentration. This transport is accomplished by the application of

Table 7.
Operating Parameters for Spiral-Wound Reverse Osmosis Study at 75% Recovery at Mocanaqua, Pennsylvania

Parameter	*Value*
Raw water feed flow, gpm	6.02
Product water flow, gpm	4.50
Brine water discharged, gpm	1.52
Brine water recycled, gpm	4.26
Minimum brine product flow ratio (Tubes 1 and 2), ratio module	5:1
Maximum brine product flow ratio (Tube 3), ratio module	12:1
Water recovery, %	74.8
Recovery of blended feed, %	43.8
Feed pressure, psig	602.
Feed water temperature, °F	62.6
Tube one flux, gal./ft.^{2}/day at 600 psi net and 77°F	19.56
Tube two flux, gal. ft.^{2}/day at 600 psi net and 77°F	19.52
Tube three flux, gal. ft.^{2}, day at 600 psi net and 77°F	18.77
Length of run, hours	1,672.

All values are means from 73 data sets.
Note: To convert flux (gal./ft.^{2}/day at 600 psi and 77°F) to liters/m^2 day at 4,138 kN/m^2 and 25°C, multiply by 40.67; to convert gal. min. to liters/sec., multiply by 0.063; and to convert psi to kN/m^2, divide by 0.145.

pressure to the concentrated solution. The semi-permeable membrane selectively refuses to allow the majority of pollutants in AMD to permeate to the product side of the membrane. Of course, this explanation is a gross simplification but is sufficient to allow visualization of the process by those who are unfamiliar with it.

A great deal of study has been devoted to reverse osmosis (RO) treatment of AMD because of its ability to demineralize the water and produce a high-quality effluent. The versatility of reverse osmosis technology allows modification of the operating parameters to enable "tailoring" the product to the desired quality level. By such techniques, reverse osmosis can generally produce potable (with the exception of *p*H) water from AMD. Very minimal lime addition is sufficient to increase the product *p*H to acceptable values.

Results of an application of RO treatment to a ferrous-iron AMD in Mocanaqua, Pennsylvania, are given in Table 7. Chemical data are presented in Table 2—Example Seven. Current estimates of RO treatment costs for AMD range from $0.75 to $2.00/1,000 gal. depending upon a wide variety of factors. These costs do not include treatment and disposal of the highly-polluting waste-brine stream resulting from RO treatment.

ION EXCHANGE TREATMENT

Ion exchange is "a reversible exchange of ions between a solid and a liquid in which there is no substantial change in the structure of the solid. In this definition, the solid is the ion-exchange material (resin)."[4]

Several ion exchange applications to AMD treatment are currently in operation in Pennsylvania. EPA is presently expanding the results of bench-scale research[3] to pilot-scale to evaluate potable water production by a different process than is currently in use.

The ion exchange process involves the use of a 2-resin system; the first resin being an H^+-form, strong-acid cation exchanger and the second resin being a weak-base anion exchanger in the free-base (OH^-) form.

In the cation column, H^+ ions are exchanged for the metal ions (iron, aluminum, magnesium, calcium,

*Based upon $100/ton cost of 50/50 NaOH and diluting on-site to 20% by weight.

manganese, etc.) in the AMD. Since the only anion in AMD is typically sulfate, the cation effluent becomes predominately H_2SO_4 with residual concentrations of metals.

The sulfuric acid solution enters the weak base anion exchanger when the acid is sorbed by the resin and hydroxyl ions are substituted. A weak-base anion exchanger cannot split neutral salts, however, and some carry-over exists of metal salts that were not removed by the cation exchanger and pass unaffected through the anion column.

As the anion effluent contains residual levels of iron and manganese, it must be further treated to meet potability requirements. This is accomplished by lime neutralization to *p*H 9 or 10, followed by filtration, followed by *p*H readjustment back to neutral levels. A small portion of the cation effluent is added to the filtered effluent to reduce the *p*H to acceptable values.

Either hydrochloric acid or sulfuric acid may be used for regenerating the cation column; sodium hydroxide is used for the anion column.

This ion exchange process produces a potable effluent. It is a process similar in application and effectiveness to reverse osmosis treatment coupled with postneutralization. The problems with the process are similar to reverse osmosis and are, namely, cost, residue treatment, and disposal.

A theoretical example of the expected capability of this ion exchange system is given in Table 8 (operating parameters) and Table 2—Example 8 (chemical data) where the RO raw feed quality was chosen as an example. Chemical cost in this illustration was around $1.00/1,000 gal. As in the case of RO treatment, the waste streams will be difficult to treat.

SUMMARY

Lime and limestone neutralization processes are the most economical methods for AMD treatment. The effluent waters are suitable for aquatic life but not for domestic or industrial use. Lime-soda softening produces an effluent suitable for selected industrial uses and for augmenting a high-quality drinking water supply, but not suitable for potable use, per se. Alumina-lime-soda is capable of producing a potable effluent. Reverse osmosis is also capable of producing a potable effluent. The costs for the respective processes increase with improving effluent quality. Ion exchange is generally comparable to reverse osmosis in effectiveness, cost, and application to AMD treatment.

The problems associated with each of these processes were not strongly emphasized in these discussions. In each instance, the major concern is the treatment and/or disposal of the reject stream whether it be in the form of sludge from the neutralization processes, waste brine from reverse osmosis treatment, or waste regenerant from ion exchange treatment. The term "potable" as used in this report assumes postchlorination.

CONCERN ABOUT TDS LEVELS

Sponsors are cautioned that some of the observations made for cases discussed below may reflect dated material, and in not every case was the information checked by the company concerned. There may be erroneous information and mis-interpretation, and this text should not by any means be followed blindly.

Although precipitation of metals by lime, limestone, NaOH, etc. followed by solid/liquid separation and clarification removes most metals, there is an increasing concern in some parts of the world as to the levels of TDS in the treated effluent, i.e., levels of $SO_4^=$, alkali metals, Cl^-, etc. In South Africa on the Witwatersrand, TDS in the regional water supply, the Vaal Dam, even after conventional treatment by the Rand Water Board, is rising steadily. TDS in minewater and possible drainage/seepage from mill tailings and wasterock dumps is of concern. This investigation found two items of interest in this respect; first is an innovative application of reverse osmosis which avoids membrane fouling problems through the use of a seeded slurry recycle; the second is an alumina-lime-soda process which appears able to reduce sulfate levels in AMD to around 250 ppm.

HIGH DENSITY SLUDGE PROCESS

For large flows of AMD with high precipitable salt loads, particularly those with high iron levels, by far the most effective and practical approach is the high density sludge process which was first developed by P. D. Kostenbader and G. F. Haines of the Bethlehem Steel Corporation.

What is the HDS Process?

HDS is lime neutralization of acid mine drainage to precipitate metals with two added features:

- Recycle of a controlled amount of precipitate sludge.
- Premixing of lime with recycled precipitate sludge to yield a high density sludge seed which is then added to the stream to be treated, as opposed to direct lime addition.

Sludge recycle to the reaction tanks where lime and effluent are added does not constitute the HDS process.

The HDS process has several advantages, the most important of which are:

1) The HDS process yields a compact high density sludge compared with conventional lime precipitation. HDS can achieve sludge densities of 20-50% solids compared with conventional precipitation which achieves only 1-3% solids.

2) HDS sludge, when disposed of, yields a stable, dry residue.

3) HDS sludge, when mixed with power plant fly ash or other pozzolans and lime, yields a dry residue which passes the EP leach test for disposal as a non-hazardous waste on a sanitary landfill.

4) Iron and the most common base metals can all be precipitated at the same pH, as described by HERMAN (?).

5) HDS results in enhanced manganese removal from effluent streams at a lower pH than conventional lime precipitation, which also yields a high density sludge, even in the absence of iron. Conventional lime precipitation of manganese works best when iron is present.

6) HDS has been demonstrated in the laboratory to achieve lower concentrations of base and heavy metals than would be predicted by solubility data, even in the absence of iron, although coprecipitation with iron allows precipitation at a lower pH and eliminates the amphoteric properties of the precipitated base metal hydroxides.

The Bethlehem Steel Corp. points out that conventionally neutralized minewater yields small precipitate particles of less than three microns with a very high surface area and energy. These attract hydrated water, and so a high energy process is needed to dewater the precipitate, e.g., a filter press or the use of a lot of polymer and a belt press. The same is said to apply to the Lectroclear flotation sludges.

HDS, on the other hand, builds up layers like an onion, and it is possible to use a vacuum filter without a flocculant to make a friable filter cake.

HDS sludge filters well on an ultra high-rate sand filter, and HERMAN (1984, personal communication) pointed out that a filtration rate in excess of 4 gpm/ft^2 can be achieved.

Since the Bethlehem Steel Corp. offers knowhow and HDS treatment design services, they do not reveal all aspects of their knowledge about the process and how to scale a plant. More details on the availability of HDS technology and services is available from:

ENVIRONMENTAL CONTROL

Mine and tailings effluent treatment at the Kimberley, B.C. operations of Cominco Ltd.

W.J. KUIT
Senior Research Chemist
Cominco Ltd.
Trail, B.C.

ABSTRACT

Complex facilities which provide for the collection, management and treatment of effluents emanating from the Sullivan mine and concentrator tailings were made operational in October 1979. Key features of the system are the use of upgraded tailings ponds for the storage of up to 800 million litres of metals-contaminated effluents, a treatment plant employing lime in a high-density sludge process and a sludge-impoundment facility designed for maximum long-term environmental safety. The completed works are capable of satisfying a difficult range of operating requirements imposed by highly variable weather conditions, drainage flows and soluble metals loadings. Final capital expenditures for the project approached $10 million and annual operating costs are about $0.8 million.

This paper discusses the Kimberley effluents treatment project and the major considerations in its development. The treatment process, major plant equipment and initial operating experience are also described.

Introduction

Cominco Ltd. has worked the Sullivan orebody at Kimberley, B.C. since 1909 and has operated a concentrator some 5 km distant from the mine since 1923. Over the last 70 years, in excess of 120 million tonnes of ore have been mined, and production continues at an average rate of 6,500 tonnes per day. It is a well-known fact that the contribution of this operation to Canada's mining industry and, in particular, Cominco's development has been significant. However, this success has not been without some undesirable side effects.

Unfortunately, the Sullivan is one of only a few major Western Canadian orebodies which may be classed as "acidic" in nature. That is, the primary economic minerals, galena and marmatite, are enclosed in a siliceous host rock with abundant pyrrhotite, but with little or no accompanying alkaline gangue minerals such as calcite and dolomite. The unavoidable consequence of mining such an ore is that contact with air and water generates an acid mine drainage containing various soluble metals orginally present as minerals.

This problem also arises in the concentrator's tailings ponds, which, in the case of the Sullivan, are two separate impoundments of different materials. The 1,100 tonnes/day of "iron" tailings are primarily pyrrhotite which is surplus to the requirements of a separate operation that produces sulphuric acid as an intermediate to phosphate fertilizers. Inert gangue minerals with only a minor sulphide content are the main constituents of the 1,200 tonnes/day of siliceous tailings. Corresponding to the relative proportion of sulphides in the solids, the decant from the iron tailings is substantially more contaminated than that from the siliceous pond.

Until 1979, both the mine and tailings effluents eventually reported to the St. Mary River, south of Kimberley, without treatment. A noteworthy feature of these effluents, however, is that the principal contaminant is soluble iron with smaller proportions of the more toxic heavy metals, such as lead and zinc. Biological monitoring in the river downstream from the effluents' points of entry has continued to show an abundance of aquatic life forms, and the concentrations of heavy metals have been far below acutely toxic values even without treatment. The impact most evident has been discoloration of stream beds by iron staining.

Cominco was originally issued an effluent discharge permit in 1967 under terms of the B.C. Pollution Control Act, which was promulgated in the same year. A subsequent amendment required the company to undertake treatment of the mine and concentrator effluents to specified values by the end of 1977. Studies were started in 1974 with the intent of meeting this objective, but it was not achieved due to a number of delays, some of which were beyond Cominco's control. An application to extend the compliance date to December 31, 1979 was eventually successful and the facilities constructed to satisfy permit requirements were officially commissioned on October 19, 1979.

Mine and Concentrator Effluents

As is common in most mining operations, the Sullivan mine drainage is a combination of surface water that has infiltrated

W.J. Kuit

Walter J. Kuit was born and educated in British Columbia and, since graduation in chemistry in 1966, has been employed by Cominco Ltd. He has conducted a range of chemical and metallurgical research assignments which, since 1972, have been mainly related to process development for effluent control from mining and metallurgical operations. His experience has also ranged from external consulting activities to field supervision of effluent treatment operations. He is currently senior research chemist at Cominco's Technical Research Centre in Trail, with main responsibilities for effluent treatment and chemical process research.

Keywords: Environmental control, Effluent treatment, Tailings, Cominco Ltd., Water treatment plants, Lime, Flocculents, Clarifiers, Impoundment.

through the fractured orebody and that pumped in for drilling. The drainage leaves the mine through the 3900 level portal, and about 70% of the total flow is intercepted and discharged by gravity. Water penetrating the lower levels is collected in sumps and pumped a total lift of 480 m to the 3900-level ditch. The cyclic nature of the lower-level drainage pumping normally causes substantial instantaneous variation in the mine discharge rate. Retention in the mine's natural hydraulic system is such that the full impact of high surface infiltration rates requires at least one week to be reflected in drainage volumes. The average annual discharge rate is about 3,000 L/min. in a rage of 1,200-10,000 L/min. Typical soluble metals concentrations and other properties of the mine drainage are given in Table 1.

Periods of high flow and high metals concentrations often are simultaneous, such as in the spring freshet due to a "flushing" of sulphate salts accumulated in rock fractures. Virtually all of the dominant parameter, soluble Fe, is present in the ferrous (Fe^{++}) oxidation state.

Prior to this project, the drainage was acutely visible to the community of Kimberley, as it directly discharged to Mark Creek, which flows through the town before entering the St. Mary River. Because both the city and Cominco draw water from an upstream location on the creek, the mine drainage has been a substantial proportion of the total flow during dry periods.

TABLE 1. Mine drainage properties

Parameter	Range
Fe, mg/L	200 - 1,000
Zn, mg/L	30 - 200
Mn, mg/L	20 - 75
Al, mg/L	35 - 150
Pb, mg/L	2 - 5
Suspended Solids, mg/L	200 - 900
pH	2.8 - 4.0
Temperature, °C	8 - 12

TABLE 2. Iron tailings decant properties

Parameter	Range
Fe, mg/L	300 - 2,500
Zn, mg/L	10 - 50
Mn, mg/L	5 - 30
Pb, mg/L	2 - 8
Suspended Solids, mg/L	25 - 100
pH	3 - 4.5
Temperature, °C	0 - 15

FIGURE 1. Lime process alternatives.

The impact of precipitation and run-off is even more severe on the decant volumes from the concentrator's iron and siliceous tailings ponds, which cover areas of 240 and 112 hectares (590 and 280 acres) respectively. Rapid snow melt during warm spring days and heavy rains cause extremely high rates of water influx that can change, virtually on an hourly basis. Dyke protection has, until the present, dictated that the decant pool sizes be minimized and, consequently, little or no attenuation of these flows was possible.

The quality of the effluents from these two sources is quite different. Because the siliceous tailings are largely inert gangue minerals, decant from this pond usually contains only minor contamination, but soluble Mn and Fe concentrations can reach 15 mg/L and 75 mg/L, respectively, on rare occasions. As a rule, the pH is near 7.0 and most bio-assays fail to demonstrate acute toxicity. Instantaneous maximum decant flows can approach 23,000 L/min., but the annual average is about 4,000 L/min.

Decant from the iron tailings is, as would be expected, significantly more contaminated, because the 240 hectares surface area of essentially pyrrhotite is for the most part exposed to the atmosphere. Oxidation generates the same soluble metals as are present in the mine drainage, but in different proportions, and Fe is even more dominant, as Table 2 indicates.

An important feature (with respect to treatment) corresponding with the mine drainage is that all of the Fe is present in the ferrous (Fe^{++}) form. Peak instantaneous flows of 55,000 L/min. have been recorded, but 6,000 L/min. is a typical annual average.

Both tailings decants have been transported by 0.64-m (24-in.) clay-tile piping to adjacent Parshall flumes south of the ponds. There combined, the flows formed James Creek, which discharged into the St. Mary River.

Effluents Treatment Alternatives

Studies originally commenced in 1974 were primarily directed toward developing the most viable process option for the treatment of mine drainage alone, because this was, at the time, considered to be the most urgent effluent problem. This was soon followed in 1975 by a change in scope to incorporate tailings effluent treatment, and several engineering studies ensued. The complexity of the project increased substantially as it became evident that options were available in the following key areas:

(1) treatment process;
(2) location of treatment facilities; and
(3) plant flow design—single or split stream.

Treatment Process

Preliminary investigations were conducted at Cominco's Technical Research Centre on a variety of treatment methods, but it became clear that viability could only be achieved using lime as a neutralizing reagent and metal precipitant. The relevant chemistry has been well documented and a review here is not required, but the practical process options merit discussion.

The first scheme, outlined in Figure 1, essentially involves the addition of lime to the contaminated effluents and mixture with a concentrator's tailings discharge. Sludge solids clarification and storage is then an integral part of tailings impoundment. Very low in cost and applied successfully at other operations, such as Heath Steele Mines[1], it was evaluated as being technically unsuitable for use at Kimberley.

The direct "mechanical" process requires an independent plant incorporating a major vessel for lime reaction and aeration (to oxidize Fe^{++} to the more stable Fe^{+++} state), followed by a clarifier or settling pond. Although widely used and highly efficient with respect to achieving good final effluent

quality, the process can suffer from a difficult-to-manage sludge handling problem due to low solids densities. This factor can be particularly severe where high soluble metals concentrations are involved. One mine drainage treatment operation has been documented in which the volume of sludge generated was up to 80% of the effluent volume treated[2].

The high-density sludge (HDS) version of the basic lime process offers the attractive potential for minimizing waste sludge volumes and was intensively researched for application at Kimberley. Originally discussed by Kostenbader and Haines[3], the HDS process recycles a substantial proportion of clarifier underflow (U/F) sludge, which is blended with lime slurry required for neutralization prior to the main reaction vessel. This pre-mix is a key function in achieving an inherent modification of sludge solids from a fluffy slime to an almost particulate texture. Incentive for the process is illustrated by Table 3, which correlates the daily volume of sludge to be handled by a facility operating at various U/F consistencies. Calculated values are from a Kimberley case of treatment at 18,000 L/min. and 1 g/L sludge solids production. The impact of this data plant operation and sludge disposal requirements is readily evident.

TABLE 3. Sludge volume - solids content relationship

U/F Solids, Weight %	U/F Volume, L/Day
2	1,310,000
5	505,000
10	245,000
20	119,000
30	75,000

HDS process superiority was confirmed in extensive continuous-flow "mini-plant" studies with a small unit operating at up to 1 L/min. Both the B.C. Pollution Control Branch permit requires and the Federal Guidelines for the mining industry could be satisfied on the full range of Kimberley effluents. Furthermore, the excellent sludge properties arising from recycle were accompanied by near complete control of gypsum scaling as an additional benefit of higher solids loading.

FIGURE 2. Effluents management and treatment.

Treatment Plant Locations

The process studies clearly defined lime-HDS as the treatment system of choice, but plant location was a question to be resolved. Included as important criteria influencing site selection were a recognition of the needs for safe sludge impoundment and sufficient system flexibility to handle long-term treatment requirements.

Separate plants to treat mine and tailings effluents were evaluated in engineering studies, which firmly concluded that such a strategy would not be viable. Costs were extremely high and serious technical differencies became apparent, particularly with respect to the mine plant. Another proposal consisted of a single facility to handle all effluents located near the tailings ponds with direct piping of the mine drainage to the plant. However, sludge impoundment in either of the tailings ponds was not practicable and ground conditions in the vicinity were found to be unfavourable for the construction of a separate diked storage area.

Soon thereafter, locating the plant immediately adjacent to the St. Mary River, about 8 km south of the mine and 3 km southwest of the tailings ponds, became a viable option. A substantial area of land across the river was found to be suitable for long-term sludge storage requirements. Separate piping of the mine and tailings effluents to the river location was a feature of this proposal.

Flow Design Concept

The river location study was completed through to the engineering feasibility level on the basis of a "twin-gut" treatment plant. That is, the retention requirements of key components such as reaction vessels and clarifier were split between duplicated systems to ensure maximum facility reliability. Without the capacity to store exceptionally large volumes of contaminated effluents ahead of the plant, this design concept would at least provide a "compromise level" of treatment in the event of mechanical breakdowns. The design treatment capacity of the plant was 18,000 L/min. (14,000 L/min. annual average rate), which could be forced to 27,000 L/min. with some sacrifice in effluent quality.

However, the problem of dealing with rates above 27,000 L/min. during the spring freshet remained, and the operation was to be scheduled on the basis of the following order of treatment priorities: mine drainage > iron tailings decant > siliceous tailings decant. Substantial volumes of untreated effluent would have been discharged annually, and the need for correcting this deficiency and simplifying the plant operation was recognized. Therefore, Dames and Moore was retained to study the feasibility of actually using the tailings ponds to store effluents and regulate their discharge. This investigation, which proved the concept to be technically sound and viable, permitted the plant design to be reduced to a "single-gut" system with improved costs and superior reliability.

FIGURE 3. Drainage water flow management.

Subsequently, the project was mobilized starting in January 1978, and construction was largely completed by the late summer of 1979. Important locations in the Kimberley system are illustrated in Figure 2, and features within the major scope areas will now be described.

Effluent Collection and Management

Mine Drainage

The collection system at the mine provides for the pick-up of the major effluent (3900 level drainage), mine dry septic tank overflow and miscellaneous waste dump drainages. Prior to being piped to the "iron pond", the flow is passed through a "grit chamber" which consists of parallel rectangular settling tanks for the capture of heavy solids which might otherwise settle and accumulate in the line at low flow rates. The pipeline is constructed of 0.36-m (14-in.) diameter polyethylene and extends for 6,900 m to the iron pond, with Air-Vac and blinded drain valves built in at strategic locations. Its design capacity is 11,500 L/min. under gravitational head alone. The line is fitted for "pig" injection and recovery, a procedure which is routinely implemented with a radio tracer-equipped Polypig.

Effluents Management

Creation of a water management capability in the tailings ponds has required a major dyke upgrading program. The lifts placed have been designed for the safe retention of about 2 m of additional hydraulic load. Compacted siliceous tailings were used for construction, with volumes of 124,000 m^3 and 36,000 m^3 being placed on the existing iron and siliceous dyke structures, respectively.

The objectives of the pond storage system are illustrated in Figure 3 (maximum instantaneous pond influx rate are indicated to emphasize the importance of flow management). About 800 x 10^6L capacity has been provided for the control of peak freshet volumes. It is expected that during spring, the treatment plant will operate at a 27,000 L/min. rate for periods of time which are essentially controlled by weather conditions. Effluents storage will permit plant shutdowns for maintenance and some degree of "blend-optimization" of the different strength decants. Additional benefits are the levelling of strength fluctuations and improved suspended solids control.

The effluents management phase of the project was not fully complete until the late spring of 1980, when remote control valve assemblies in the decant structures were made operational. These allow full flow control from the treatment plant and prevent fluctuations that would otherwise be caused by relatively small head changes.

Treatment Plant Feed

The two pond effluents are directed through the existing decant lines and flow measuring flumes which are recorded in the plant. They are then combined in a junction box which is designed to allow dumping of the less contaminated siliceous decant in emergency situations. The James Creek pipeline varies from 0.46 m (18 in.) to 0.56 m (22 in.) over a total length of 3,600 m. It is designed for a maximum flow of 34,000 L/min. and is fitted with protective devices similar to those on the mine drainage line.

The combined effluents flow discharges to a 900,000-L-capacity surge tank constructed of acid-resistant concrete at the plant site which is operated by level control instrumentation. Storage of the effluent volume contained in the James Creek line will be possible in the event of a forced plant shutdown, or this vessel can be bypassed with the flow going directly to the plant.

Effluents Treatment Plant

Design is based on achieving optimum performance at a normal maximum of 18,000 L/min., but operation at a forced rate

FIGURE 4. Kimberley drainage treatment—process flowsheet.

of 27,000 L/min. during the spring can be managed. The key reagent supply systems (lime, air, flocculant) are sized on the basis of forecast peak demand, but shortened retention times may cause some deterioration in final effluent quality. Process design was based on extensive mini-plant testing conducted previously at Cominco's Technical Research Centre in Trail, B.C. All possible operating parameters, including effluent temperatures as low as 0°C, were simulated in the small-scale unit, which obviated the need for pilot-plant confirmation.

Plant Process

The process flowsheet and ranges of major parameters associated with the operation are illustrated in Figure 4. Important features of the system will now be reviewed.

Lime slurry and recycled clarifer U/F sludge are blended in the sludge/lime mix tank at the head of the process. This step is of vital importance with respect to maintaining satisfactory sludge properties. The sludge/lime mixture discharges to the rapid mix tank, which achieves a partial neutralization of the contaminated effluent entering the plant. Smooth final pH control at the optimum value of 9.5 in the subsequent large reaction tank depends on feed-back regulation of the lime slurry based on the pH in the vessel.

The principal treatment tank, the lime reactor, provides a retention time of about 50 min. at the maximum combined flow of raw effluent and sludge recycle. Near complete precipitation of metals as hydroxides occurs directly at this stage according to:

$$(Zn^{++}, Pb^{++}, Mn^{++})\,MSO_4 + Ca(OH)_2 \xrightarrow{H_2O} M(OH)_2 + CaSO_4 2H_2O \quad (1)$$

$$(Al^{+++}, Fe^{+++})\,M_2(SO_4)_3 + 3Ca(OH)_2 \xrightarrow{H_2O} 2M(OH)_3 + 3CaSO_4 2H_2O \quad (2)$$

However, optimum process chemistry and physical performance require complete oxidation of ferrous hydroxide to the more stable ferric hydroxide as indicated by:

$$Fe(OH)_2 + \tfrac{1}{4} O_2 \rightarrow Fe(OH)_3 \quad (3)$$

Virtually all of the plant feed soluble iron is in the Fe^{++} form, and oxidation by aeration under high shear agitation provides the following:

Optimum Chemistry—Co-precipitation and absorption phenomena associated with $Fe(OH)_3$ formation result in lower soluble heavy metals concentrations than those derived from hydroxides alone.

Clarifier Performance—"Oxidized iron" solids exhibit superior settling properties and form a sludge that is much less viscous than the non-oxidized solids.

Sludge Stability—Incomplete Fe^{++} oxidation during treatment can result in chemical instability of impounded sludge and re-dissolution of heavy metals.

With the chemical reactions completed, the discharge from the lime reactor is treated with dilute flocculant solution prior to entering the gently agitated floc mix tank. This vessel was incorporated into the process to ensure good floc formation prior to clarification.

The clarifier O/F discharge to the river is monitored for flow rate, turbidity and pH, with daily composite samples taken for metals analyses. Thickened U/F sludge of about 20-30% solids content (250-350 g/L) is then either recycled or purged to the impoundment area. The recycle rates are so controlled that 10-20 Kg of solids are returned to the head of the process for every Kg precipitated from the plant feed. Therefore, 90-95% of the solids loading in the system is recycled material.

The frequency and duration of sludge purging is determined by the rate of production. Under peak metals loading to the plant, the frequency can be once every day for a maximum of 6 hours of pumping. A total solids inventory of about 200 tonnes is probably the operating maximum that can be ac-

TABLE 4. Typical operating parameters

lime (CaO) consumption:	20 tonnes/day
flocculant consumption:	(3 mg/L) 80 Kg/day)
sludge solids production:	26 tonnes/day
sludge volume production:	(250 g/L) 104,000 L/day)
recycle rate:	(15/1) 1,100 L/min.
sludge purge frequency:	once (150 tonnes) every 6 days

cumulated without having a detrimental impact on the plant (i.e. clarity, clarifier mechanism torque).

Operating parameters will vary greatly, but typical conditions can be illustrated from the plant treating 14,000 L/min. containing, as the major soluble metal, 400 mg/L Fe.

Plant Equipment

The general arrangement of the main plant components is illustrated in Figure 5. A fundamental design criterion of the facility was that it eventually should function with a minimum of attention, including periods when an operator would not be present. Therefore, manual labour requirements in the plant are minimal, with key systems being duplicated and interlocked.

Lime System—Twin 140-tonne silos equipped with bin activators provide pulverized quicklime storage. Screw feeders of 15 cm (6 in.) diameter supply BIF slakers, which are each rated at 3,200 Kg/hr. lime, producing a slurry of about 15% consistency. This is stored in an agitated tank below floor level which has 1.5 hour storage capacity at the peak lime demand of about 100 tonnes/day. Interlocked 15-hp Morris vertical pumps, rated at 900 L/min. each, supply the pressure-controlled lime feed loop.

Flocculant System—The two interlocked flocculant solution preparation and feeding packages are automated and utilize the BIF Polypac systems. These disperse dry flocculant particles by the drum-wetting principle to ensure solution preparation with minimal "fish-eye" formation. The feed hoppers of each unit are occasionally charged by a Vac-U-Max loading system from ground-level storage. Metering pumps feed solution at 5 g/L concentration, and this is reduced to 0.25 g/L with fresh water in a Kenics static mixer before application.

Air Supply—Three 75-hp Gardner-Denver "cyclo-blowers" are installed below the elevated rapid mix tank to supply air for iron oxidation in the lime reactor. Each has a capacity of about 21 m³ (750 cf)/min. at 100 KPa (15 psi). Normal plant operation will utilize only one blower, with two being on line during peak requirements. The third is intended as a stand-by unit during this period.

Process Tanks—The main process flow through the plant (sludge/lime mix to clarifier) is by insulated launders which are designed for 34,000 L/min.

Sludge/Lime Mix	: Mild steel construction, 3.6 m dia. by 3.9 m, 10-hp Denver, spindle bearing agitator.
Rapid Mix	: Stainless construction, 4.2 m dia. by 3.9 m, 15-hp Denver, spindle bearing agitator.
Lime Reactor	: Concrete construction, 15.2 m dia. by 9.7 m, 150-hp Lightnin, reducer drive, 48 rpm. Flat-blade disk turbine impellor, 2.1 m dia. (crown plate distributor below turbine.)
Flocculant Mix	: Concrete construction, 4.8 m dia. by 4.2 m, 3-hp Denver, reducer agitator.

FIGURE 5. Treatment plant arrangement.

Clarifier—The vessel is concrete and measures 36 m dia. by 3 m. Peripheral O/F is provided by submerged ports, with a weir controlling the level, and the vessel is designed to operate with an ice cover. The mechanism is an Envirotech-Eimco type B heavy-duty unit operating at .08 rpm. One 5-hp drive is installed, which gives a torque rating of 240,000 Nm (175,000 ft lb), but this can be doubled by the installation of a second drive. The rake blades are attached to the arms by 0.7-m "thixo-posts", a design that facilitates raking of the viscous sludge. An automatic rake lifting and lowering system is another feature of the mechanism.

Clarifier U/F Handling—Two independent pumping systems are located in a service tunnel beneath the clarifier.

Sludge recycle is by two Canadian Allis Chalmers SRL pumps driven by interlocked 25-hp Asea D.C. variable-speed motors. The capacity of each is 3,800 L/min. under an 18-m head. Separate 20-cm (8-in.) lines feed a nuclear densitometer-equipped Parshall flume, which discharges directly to the sludge/lime mix tank. The recycle system is also designed to fill and pump from the 6-m-dia. by 6-m emergency sludge storage tank shown in Figure 5. This feature will only be used in the event of a plant shutdown which requires the clarifier to be emptied. A stock of dense sludge is a process necessity to ensure that equilibrium operating performance prevails immediately after the plant is re-started.

Sludge purging to storage about 700 m from the plant is done with parallel 60-hp Morris SRL pumps capable of pumping 4,000 L/min. of the thixotropic material. Additional lime, equivalent to approximately 4% of the sludge solids, is added to the sludge during discharge. The two 15-cm (6-in.) diameter, insulated steel lines have four primary discharge locations in the impoundment area and are graded to drain back to the plant. Clarifier O/F is used to flush the lines following each purge.

Sludge Impoundment

The sludge impoundment facility in current use will provide a minimum of 5 years storage capacity based on an average volume accumulation of 55,000 m³/year. Only modest dyke construction, requiring 19,000 m³ of local borrow material, was necessary to provide this Stage I storage capacity. Further development of the site can provide sludge impoundment for in the order of 90 years of plant operation if required. A practical utilization method for this material is obviously desirable, and this search will continue.

It must be emphasized that the impoundment technique is not one of slurry ponding. There is no decant from the stored sludge, as the underlying ground is a mixture of sand and cobble which provides good drainage characteristics without solids escape. Studies have demonstrated that the rapid drainage of water originally present in the sludge or from subsequent precipitation is essential to the development of properties that will ensure long-term environmental safety.

The desired changes which occur in sludge discharged to the impoundment area are illustrated in Figure 6. Initially, the material naturally de-waters to about 50% solids, with the drainage reporting to the water table and eventually the St. Mary River. The quality of the drainage water is the same as that which the plant directly discharges to the river, and this is being monitored by sampling from wells installed at strategic locations. During the winter, freezing of the sludge is a limiting factor, but this effect results in enhanced drainage characteristics following spring thaw. Summer drying removes additional moisture, causing shrinkage which allows the ingress of air. This initiates the function of the extra lime intentionally added before discharge from the plant. Atmospheric

carbon dioxide (CO_2) reacts with the lime, forming a calcium carbonate ($CaCO_3$) matrix in the relatively porous solids, thus providing a measure of physical stability and assisting the permanent fixation of heavy metals. Table 5 illustrates a typical chemical analysis of the sludge, showing the significant metals present.

The discharge points in the impoundment area are cycled to give deposited sludge the maximum exposure time possible before being covered by fresh material. Lengthy cycle times are augmented by the plant's capacity to store sludge solids with only intermittent purging. Leach tests on sludge which has undergone this impoundment cycle have yielded virtually no dissolution of heavy metals under the range of natural conditions prevalent in the area.

Operating Experience

As the facilities have been operational for only about one year, a full assessment of long-term performance cannot be made at this time. At least several years will be required to confirm water management and treatment plant capabilities under the complete range of operating demands.

Mine drainage piping to the iron tailings pond was operational in April 1979, and this system has performed satisfactorily, achieving an immediate improvement in the quality of Mark Creek water which has drawn favourable community reaction.

Plant Operation

The initial operating trials commenced in early September and the plant was officially commissioned on October 19, 1979. An operator and a helper initially manned the plant on each shift, seven days per week, but the complement is now one man per shift and further reductions are planned.

The time requirement for bringing the HDS treatment process to an operating equilibrium was not experienced in the Kimberley plant start-up due to a rather unusual method of preparation. This involved obtaining about 110 tonnes of sludge containing 40% solids from The Bunker Hill Co., Kellogg, Idaho, which operates a similar treatment process[9]. "Seeding" the system using this material proved to be highly effective, as the fresh sludge produced was immediately about 20% solids and high consistencies were readily maintained. The plant initially operated for a period of two weeks at an average feed rate of 10,000 L/min., producing 11 tpd solids, before any sludge was purged to storage.

The over-all operating performance of the facility has been highly satisfactory and the break-in problems normally prevalent in a new plant have been minimal. Key mechanical systems, such as those supplying reagents, and the process control instrumentation have generally operated very well. From the outset, there were no process or mechanical difficulties that prevented the plant from being fully operational. Scheduled shutdowns have been necessary for several minor modifications, but effluents were stored in the ponds during these periods.

Some difficulty was initially experienced with the lime reactor agitator in that the power draw was unacceptably high with only one blower running. Two blowers (42 m^3/min. air) had to be run continuously to ensure sustained operation of the agitator, but this was corrected by reducing the impeller diameter from 2.13 m (84 in.) to 2.06 m (81 in.). Another minor deficiency soon apparent was an inadequate degree of fluid motion in the sludge/lime mix tank caused by the thixotropic properties of the recycled sludge. Air injection to augment the agitator was necessary, but merely removing the tank baffles and increasing the agitator speed corrected the problem.

FIGURE 6. Changes in impoundment sludge.

TABLE 5. Metals content of sludge

Metal	Weight %
Fe	19.5
Ca	9.5
Mg	6.0
Si	3.1
Zn	2.1
Al	1.8
Mn	1.2
Pb	0.3

Development work on the flocculant application system was effective in resolving a slight deficiency with respect to clarity of the plant discharge that developed folowing start-up. Operation with clarifier O/F suspended solids concentrations of about 25 mg/L was found to be "aesthetically" unsatisfactory, even though it was within the permit requirements. The use of one of several efficient anionic flocculants in a split application method (Fig. 4) now produces suspended solids values of consistently less than 15 mg/L, with the desired visual impact.

Treatment Performance

Results from the first few months of operation have generally been gratifying. The treatment rate has thus far varied from 7,000 to 27,000 L/min., with the feed consisting of both tailings pond decants in a range of proportions. This variation has resulted in diverse feed strengths which are illustrated by the major soluble metal, Fe, being in the range of 30-500 mg/L.

The quality of the treated effluent discharged to the St. Mary River has normally been superior to that yielded by the lab-scale mini-plant studies. It is also remarkable that metals analyses of the final effluent have been very consistent and essentially independent of the loading to the plant. Performance, to this point, has been well within the standards set

TABLE 6. Plant treatment performance

Parameter, Total Values	Plant Feed	Federal Guidelines	Plant Effluent (mg/l)
Fe mg/L	250	—	<1.0
Zn mg/L	22	0.5	<0.2
Pb mg/L	5	0.2	<0.1
Cu mg/L	0.15	0.3	<.05
As mg/L	.02	0.5	<.01
Suspended Solids mg/L	75	25	<15
pH	4.5	min. 6.0	9.5

down by both Environment Canada and the B.C. Pollution Control Board. To illustrate this with an example that is meaningful to the industry across Canada, Table 6 compares the typical metals concentrations present in the plant feed and effluent with the monthly average objective values in the Federal Guidelines.

With respect to the plant's other product, impounded sludge, substantial time will naturally be required to prove long-term environmental acceptability. However, initial observations indicate that the desired drainage and consolidation are occurring satisfactorily and there is confidence that expectations will be met.

Conclusion

The completion of this project is the culmination of extensive efforts over several years by various groups within Cominco Ltd. and a capital expenditure of nearly 10 million dollars. Adding to this commitment, of course, is the anticipated annual operating cost of the facility, which will be in the order of 0.8 million dollars. It can be appreciated that these cost burdens are a particularly harsh reality when there is no opportunity for monetary return. Moreover, the operation of the treatment plant will have to be maintained long after the closure of the mine and concentrator at Kimberley, beause the oxidation and leaching of residual sulphides will continue.

However, the facilities were constructed with the objective of providing a comprehensive solution to a difficult effluents management and treatment problem, with emphasis on the criteria of reliability and process effluent quality. Value can only be derived, therefore, from the degree to which results fulfill planning. Although the operating record of the Kimberley system is only brief to this time, performance is confirming the project to be a substantial contribution to the improvement of environmental quality.

1982 ENVIRONMENTAL ENGINEERING DESIGN AWARD

Cominco Ltd is the winner of the second Environmental Engineering Design Award of the Association of Professional Engineers of BC. Cominco's Effluent Treatment Plant at the Trail Metallurgical Operation was judged the best design for 1982 and their submission is published here in full.

The Award was presented by APEBC President Ken Williams PEng to authors Roger Watson PEng and John Turnbull PEng at the West Kootenay Branch Meeting in Castlegar on March 24, 1983.

Seven other submissions were received from coal mines, pulp mills, engineering consultants, municipalities and government departments. Extracts from these submissions were prepared by Kelly Kline PEng of the Environment Committee and, with the authors' permission, are published in this issue.

1982 Environmental Engineering Design Award Winner

Cominco Ltd's Effluent Treatment Plant at its Trail, BC, Metallurgical Operation

R H Watson PEng, Manager
J D Turnbull PEng, Assistant Manager
Trail Modernization Project

INTRODUCTION. Cominco Ltd's huge metallurgical complex is located in Trail, British Columbia, a city with a population of 10,000 located in the Columbia River Valley in the West Kootenays, 18 km north of the Canada-US border. The lead-zinc production complex is the largest in the world with an annual capacity of over 400,000 tonnes combined lead and zinc. As a consequence of this installation, 30 tonnes of silver and over 325,000 tonnes of chemicals and fertilizers are produced annually. Gold, cadmium, bismuth, antimony, arsenic, and indium are also recovered as by-products.

John D Turnbull PEng, Assistant Manager, Roger H Watson PEng, Manager, Trail Modernization (centre), receive the APEBC 1982 Environmental Engineering Award from Ken Williams PEng

Trail Operations' Effluent Treatment Plant is part of the modernization and expansion program announced by Cominco in 1977. To the end of December 1982, Cominco has expended about $335-million. It is expected that the modernization program will cost in excess of $700 million when completed and that the internal and external aspects of environmental control will amount to approximately $200-million.

From its earliest days, Cominco has demonstrated a responsible corporate attitude towards the environment and has made concerted efforts to minimize the impact of its metallurgical operations on the environment. Its efforts with respect to environmental control date back to 1927 when it undertook steps to control sulphur dioxide and heavy metal particulate emissions from its smelting operation with the installation of a chamber plant to produce sulphuric acid from zinc roaster gas.

Cominco's efforts, which anticipated environmental legislation by several decades, have paid handsome environmental dividends over the years. The Columbia River at Trail has continued to be a favourite among local sportsmen whose fishing activities range from shoreline angling to trolling from boats. Fish caught above and below the Trail plants are of excellent quality and comply with Canadian and foreign standards for food as shown by studies carried out between June 1977 and October 1981. Studies concerning blood-lead levels, lung function and

general health of local residents have shown that Trail is a good place in which to live and bring up children.

NEW WASTE MANAGEMENT BRANCH REGULATIONS

Notwithstanding the fact that Columbia River water downstream from the Trail plants was well within drinking water standards for metal content, it was anticipated that new, discharge-related Waste Management Branch regulations would ultimately necessitate an effluent treatment plant. Consequently, Cominco Engineering prepared a feasibility proposal which outlined the process and plant design, project schedule and capital cost. Funds for the project were appropriated and the project team was mobilized in October, 1978.

On November 29, 1978, Cominco Ltd was issued Pollution Control Permit No PE-2753. The permit requires that the contaminant loadings in effluents discharged into the Columbia River from Trail metallurgical operations be reduced to meet specific maximum levels of contamination by January 1, 1983. The effluent treatment plant was to operate in conjunction with various metallurgical process improvements and other environmental projects to achieve the stringent quality objectives specified in this permit.

PROCESS TECHNOLOGY

The Trail Operations Effluent Treatment Plant uses the high density sludge (HDS) version of the basic lime precipitation process which was researched intensively by Cominco Ltd. Cominco's first application of this process was the $10 million Effluent Treatment Plant at its Kimberley Operations, officially opened in October 1979.

The HDS process recycles a substantial proportion of the clarifier underflow sludge. This material is blended with the lime slurry necessary for neutralization prior to mixing in the main reaction vessels. The pre-mix is an important feature of the process that modifies the physical characteristics of the sludge solids from a fluffy slime to an almost particulate texture.

In the course of pilot plant testing of Trail Operations effluent, Cominco Technical Research personnel simulated various upset conditions in order to be able to design a plant that would handle the combination of varying flow rates and effluent characteristics from various sewer systems of the complex metallurgical operation.

$9-MILLION TREATMENT PLANT

The $9-million Effluent Treatment Plant for Cominco's Trail lead-zinc operation is one of several environmental projects that ultimately will allow Cominco to meet the new Provincial environmental standards.

Because the plant is located next to a residential area, it was built with aesthetic considerations in mind. Extensie landscaping and an attractive exterior were features of the design.

The plant has a treatment capacity of 4500 litres of effluent process water per minute, but because of the incorporation of a large holding tank for incoming feed, the plant can handle emergency surges of up to 9000 litres per minute. Flows from various sewer systems from 20 separate areas at the Trail metallurgical complex are treated in the plant.

The collection system connecting the various industrial sewers to the treatment plant involved the construction of an underground gravity flow piping system. Thirteen effluent streams from the zinc operations are collected and drained to the treatment plant. The major flow from the zinc plants, roaster off-gas cooling water, is stripped to

FIGURE 1

SO_2 prior to being sent to the treatment plant, thereby minimizing sludge production. Effluent streams from the lead smelter are first collected in a thickener where they are neutralized to pH 6.5. Thickener overflow is then pumped to the plant for treatment.

Effluent streams from the lead smelter and zinc operations are received in a 23-metre diameter mild steel storage tank lined with neoprene rubber for corrosion resistance. The tank is aerated to keep the solids in suspension. Tank exhaust air is water scrubbed and the scrubber effluent water is sent to the reaction tank for neutralization. The storage tank provides a 13-hour surge capacity for blending of the varied feed streams, dilution of acid spills and allows for short-term plant maintenance shutdowns.

From the storage tank, a controlled flow of the combined effluent is pumped to the first of two 106,000-litre fibreglass reinforced plastic (FRP) reaction tanks in series, for neutralization with lime to pH 10. Both reaction tanks are baffled and agitated to ensure proper mixing.

Pulverized quicklime is received pneumatically in a 150-tonne bin from a bulk delivery truck. The bin is provided with a vibrating bin discharger bottom that ensures a continuous flow of material and prevents bridging and rat-holing in the bin. Air is exhausted via a pulse jet bag filter mounted on top of the silo.

A variable speed screw feeder meters the quicklime into a paste-type lime slaker where it is hydrated. The lime slaker is essentially a mild-steel conveyor trough in which lime and water are mixed with rotating paddles. Hydrated lime is stored as a 10% lime slurry in a 106,000-litre FRP tank. The tank has four internal baffles and is agitated to maintain a homogeneous mixture. Quicklime is drawn off the tank by centrifugal pumps and pumped to a 4000-litre capacity opened top FRP tank where it is pre-mixed with recycled clarifier underflow sludge.

The combined slurry overflows the premix tank and is mixed with the effluent in the reaction vessels where neutralization and precipitation is accomplished. The pH in the reaction tanks controls the lime slurry flow rate to the premix tank.

Neutralized effluent slurry from the reaction tanks is mixed with a flocculant in a 3500-litre mix tank which overflows to a clarifier for liquid-solid separation. The flocculant, an organic polymer, is added to improve the settling characteristics of the fine precipitate. This promotes rapid settling of the sludge particles in the clarifier producing a clear effluent overflow for discharge to the Columbia River. This overflow is continuously monitored for turbidity and pH.

The clarifier is a 25-metre diameter by 3-metre deep concrete tank with a slow moving rake mechanism that draws the settled solids to the bottom center cone while allowing incoming solids to settle undisturbed. Settled sludge is removed from the clarifier at about 25% solids. A major portion of this sludge is recycled and mixed with the lime slurry used for neutralization. The balance is pumped intermittently, depending on the sludge production rate, to the Lead Sinter Plant. In the Sinter Plant, the sludge is combined with a reclaimed lead slurry stream, dewatered on a drum filter and mixed with zinc leaching plant residue slurry for treatment and recovery of the metal values. The filtrate joins other Sinter Plant effluent streams for return to the Effluent Treatment Plant.

A simplified flow diagram of the plant is shown in Figure 1.

Interior of the main process building of the Effluent Treatment Plant showing the bottom of the lime bin and the lime slaker (beside the operator).

PLANT PERFORMANCE

Plant commissioning proceeded in an orderly manner with no major problems and the plant was started on June 8, 1981. The startup went smoothly and the maximum design rate was achieved after only three days of operation. Design limits on the discharge turbidity and pH were met from the very first day.

Since startup, the new plant has performed as expected.

Recovery of zinc, lead and cadmium from the processed streams has been good:

	% Recovered
Zinc	98.9
Lead	99.5
Cadmium	97.5
Suspended Solids	92.9

The Effluent Treatment Plant has contributed to an overall reduction in heavy metals in the effluent leaving the Trail plants. Columbia River water quality data are shown in Table I.

Operating costs have averaged $50,000 per month with lime cost contributing 40% of the total. The metals recovered in the plant, after subsequent reprocessing costs and other associated savings, serve to offset the operating costs to a large extent. Typical of most environmental control projects, there is no return on the capital invested.

An unexpected benefit of the treatment plant is that it has acted as a "policeman" to the metallurgical operation. Any short term process upsets that previously resulted in unrecognized discharges to the river are now readily detected, their origin traced and corrective action taken. During such upsets, the Effluent Treatment Plant, with its conservative design and surge capacity, acts as an effective buffer to prevent the discharge of metallic effluents to the Columbia Rover.

ENGINEERING AND CONSTRUCTION

The Effluent Treatment Plant was designed to meet the strict requirements of the BC Ministry of the Environment. The process and design specifications which served as the basis for detailed design (see Table II) were established by Cominco Technical Research and the Trail Modernization Group. Because of the environmental focus of the plant, extreme attention was paid to minimizing periods of plant downtime. As a consequence of this philosophy, features such as 100% surge capacity, double piping in certain areas, and installed standby pumps were included in the design criteria.

Project management, project services, overall design responsibility and construction were provided by Cominco Engineering. Hatch Associates Ltd of Toronto were responsible for the detailed design work while process technical services were provided by Cominco Technical Research.

The technology, design, construction and operating expertise developed as a result of this project is now being made available to third parties through Cominco Engineering Services Ltd (CESL), a wholly-owned subsidiary of Cominco Ltd.

ACKNOWLEDGEMENTS. Successful implementation of a project of this nature required the broad spectrum of technology, know-how and experience of a large number of professional engineers, technicians, technologists and specialists from within the Cominco organization. Particular acknowledgement is accorded the following key members of the project team:
P Huszti, Operations Representative
W J Kuit, Assistant Manager, Environmental Control
A R Babcock, Research Chemist
D A Burnett PEng, Project Superintendent
H M Ichiyen PEng (Ontario), Design Superintendent (Hatch Associates Ltd.)
D K MacDonald PEng (Alberta), Construction Superintendent

Table II. Effluent Treatment Plant Data

- Capital cost: $9.0-million
- Completion: June, 1981
- Effluents treated: Contaminated streams from 20 areas in Lead and Zinc Operations
- Effluent collection capacity: 4500 LPM normal; 9000 LPM surge capacity
- Surge tank: 23 metre diameter; 3.6-million litres capacity
- Lime silo: 150 tonnes quicklime
- Lime slaking capacity: 1.8 tonnes per hour
- Process
  - Feed: 4500 LPM normal; 6000 LPM maximum
  - Reactors: two in series, 20 minutes retention time each
  - Lime neutralizes acid and precipitates metal present (usage 11 tpd).
  - Flocculant: use 6 kg/d; added to assist solids settling in clarifier
- Clarifier: 25 metre diameter; 1.7-million litres capacity
- Products: clean water to river; 20 tonnes of sludge per day to Lead Smelter
- Labour: 1 operator per shift
- Operating cost: $50,000 per month

At the left is the surge tank, to its right the main process building with a tower housing the lime bin and in the foreground the clarifier from which the overflow reports to the Columbia River and the underflow back to the metallurgical plants for the recovery of metal values.

Lime in gold and uranium mining

How ERPM uses lime to solve unique underground water problem

The demand for lime in the South African gold and uranium industry is soaring as mines expand and new uses are found. This article — the first of two discussing the usage of lime in mining — describes how lime is used in a unique, high density sludge process at ERPM gold mine in a plant now regarded as highly successful and the biggest of its kind in the world.

LIME IN THE FORM of calcium oxide, slaked to calcium hydroxide, as well as agricultural lime is used extensively in the South African gold and uranium mining industry. Lime is used in the manufacture of calcium cyanide and is added to the gold bearing pulp to protect the cyanide from decomposing. It also plays an important part in settling pulp. The excess barren sulphuric acid solutions generated in the uranium extraction plants, as well as the acidic uranium residues, are neutralised with hydrated lime before being disposed of.

Iron pyrite (FeS_2) is present in gold bearing ore (conglomerate), oxidising to iron compounds which contaminate underground water. This water always requires liming, oxidation and settling before being disposed of. If the conventional neutralisation method is applied a voluminous sludge is formed, rendering disposal thereof almost impossible. The High Density Sludge (H.D.S.) process has been applied with success by Rand Mines' technical advisers to E.R.P.M. Sludges containing up to 70 g suspended solids per 100 ml suspension have been produced.

INTRODUCTION: About 34 per cent (565 000 t/a) of the total lime production in South Africa is used in the mining industry, the majority of this for the production of gold and uranium.

The South African gold bearing ores always contain iron pyrite which, on exposure, oxidises to sulphuric acid and iron sulphate, giving rise to relatively large volumes of contaminated underground water. This water must receive some kind of lime treatment before being pumped to surface. Neutralisation is necessary to prevent excessive corrosion of equipment and also to meet certain legal requirements prior to disposal. This application forms the major part of the total lime consumption in the above-mentioned industry.

The author, Dr C.M. van Staden, Pr Eng, DSc, F.S.A.I.M.M., is a consulting metallurgist at Rand Mines Limited. The articles are based on a paper he presented to the 4th International Lime Congress (Technical) held in Hershey, Pennsylvania, United States.

Pollution prevention

When the conventional method is used to neutralise underground waters with lime, voluminous sludges, which are difficult to dispose of, are obtained. A solution to the problem as encountered at the East Rand Proprietary Mines Limited (E.R.P.M.) (one of the Rand Mines Group of Mines), is described here.

In terms of the Atmospheric Pollution Prevention Act[1] it is necessary to suppress the dust caused by wind erosion from the mine's residue disposal dams. Various methods to achieve this have been tested by the Research Laboratories of the Chamber of Mines (C.O.M.), and it has been found that planting of vegetation on these dams is the most practical and suitable method. The surfaces of these dams are usually acidic due to the oxidation of pyrite contained in the deposited residue; agricultural lime and hydrated lime are used to treat the surfaces prior to and after the establishment of vegetation.

NEUTRALISATION OF UNDERGROUND WATER: Gold in South Africa is found in the conglomerate ore which was formed about 2,5 x 10^9 years ago and which consists mainly of weathered rock and quartzite pebbles. The gold content of this ore averages 9 g/t[2] with a pyrite content of between one and three per cent expressed as sulphur. Pyrite exposed underground by the mining operations is bacteriologically oxidised to yield sulphuric acid and

Sludge at ERPM after lime treatment ready for use in neutralisation of underground water.

At left, underground water with lime and no aeration; the iron is in the ferrous state. Centre, underground water with lime and aeration; the lime is in the ferric state. Right, underground water treated with the high density sludge process. All these samples are shown after 24 hours of settling. Note the same Fe content but the different sludge volumes.

water soluble iron salts. A simplified version of the oxidation process is as follows:

$$2FeS_2 + 7O_2 + 2H_2O \rightarrow 2FeSO_4 + 2H_2SO_4$$

$$2FeSO_4 + H_2SO_4 + \tfrac{1}{2}O_2 \rightarrow Fe_2(SO_4)_3 + H_2O$$

The result is fairly acidic underground water, pH 3,0, with an iron content as high as 1 500 mg/l.

To enable mining to be carried out this water must be pumped out of the mines. It is necessary to raise the pH of the water to about 5,0 to 5,5[3] (which is the critical corrosion pH for mild steel under these conditions) and thereby to protect the pumps and pipe columns underground.

The conventional lime neutralisation process is shown diagramatically in figure 1. Underground water is neutralised with milk of lime in an agitated tank. Aeration is necessary if the underground water contains ferrous iron, which must be converted to the ferric state for precipitation. The treated water flows to a settler where the ferric hydroxide is settled. The clear overflow (pH 7,5) is utilised in the reduction plant or disposed of in a public stream. The sludge is mixed with reduction plant residue and disposed of on a residue dam.

The establishment of the High Density Sludge (H.D.S.) Process at E.R.P.M.: At E.R.P.M., one of the gold mines in the Rand Mines Group, a unique problem regarding underground water pumping and treatment developed following the closure of neighbouring mines. Pumping started at the South West Vertical (S.W.V.) shaft of this mine in March 1967 at 49 level, 2 030 m below surface, and continued until February 1975. The volume of water pumped and treated was about 6 800 m³ per day. The conventional method of lime neutralisation was used (see Fig. 1.) and clarifier underflow containing about 4 g/l of suspended solids was obtained.

Before February 1975 mining operations and underground water pumping were curtailed or stopped by a number of mines in the area which was about 40 km from East to West and 10 km North to South of E.R.P.M. This had a very important effect on the underground water situation at E.R.P.M., which was still in operation and also the deepest mine in the area. It was therefore obvious that E.R.P.M. had to plan for the pumping of the additional underground water.

For economic and practical reasons it was decided to stop pumping from 49 level (which was a two stage pumping operation), plug the flow at this level by casting concrete plugs with a total overall length of 13,7 m in the drive (and other drives where necessary) and allow the water to rise behind the impervious wall to 24 level, 1 050 m below surface, from where the future pumping would be done in a single stage operation. The pumping arrangement at this level is described in detail by Tyser.[4]

Planning and Investigation

During the planning and investigation stages it was decided that provision should be made to treat an average flow of 45 454 m³/day of underground water.

Design of the surface treatment plant was based on this figure. It was also decided to partially neutralise the water underground with lime to protect the pumping equipment and pipes and for practical reasons it was decided that no settling would be done underground.

The only underground water available for experimental purposes was that from 49 level before the

Figure 1

plug was cast. It was hoped that the quality of the water would not deteriorate but rather improve during the time it took to reach 24 level. This was later found to be the case.

At the time of the test the water of 49 level had the following composition:-

pH	→ 3,2
Total dissolved solids	10 000 mg/l
Fe^{2+}	1 400 mg/l
Fe^{3+}	100 mg/l
* Precipitatable solids	5 500 mg/l

Problems encountered: The first question which had to be answered was what quantity of lime would be required, with aeration to oxidise the iron, to raise the pH of the water to 7,5.

*This represents the amount of solids in suspension after neutralisation to pH 7,5 with milk of lime and aeration to oxidise the ferrous iron completely.

Evaluation of H.D.S. process

This was determined from a graph (Fig. 2) of pH vs. amount of lime added to a litre of raw, aerated, 49 level plug water. Using this graph it can be shown that 89 t of lime, containing 90 per cent available CaO, will be required by 45 545 m^3 of underground water per day. It was found later that this figure agrees fairly well with the actual requirement.

The analysis of the 49 plug water indicated that 5 500 mg/l of precipitatable solids, which is equivalent to 250 t, had to be disposed of per day.

If the conventional process of lime treatment had been used a sludge containing a maximum of 4 g suspended solids per 100 ml suspension would have been obtained, equivalent to a sludge volume of 6 250 m^3/day. The only practical method of disposal would be to mix the sludge with gold plant residue and pump the mixture to the residue disposal dams, the sludge replacing make-up re-pulping water. The maximum volume the Reduction Plant could dispose of in this way was only 2 727 m^3/day.

Figure 2

The mine was thus faced with a serious problem, and as the inflowing water behind the plug was rising at a rate of about 0,8 m/day, a solution to the problem was urgently required.

Evaluation of the H.D.S. Process: Various methods to treat the water were considered and it was finally decided to evaluate the H.D.S.[5, 6] process developed by Bethlehem Steel, Pa., in detail. Rand Mines, entered into an agreement with that company to evaluate their process and, if suitable, to use it.

A schematic flow diagram of the H.D.S. process is shown in figure 3.

Three plants at Bethlehem Steel

The important feature are:

☐ That milk of lime must be mixed with the sludge, and this sludge-lime mixture used to neutralise the underground water on surface. If this is not done, the required sludge density is not obtained.

☐ That return sludge rate is such that 25 parts or more of solids are returned for every one part of solids that will be precipitated from the incoming underground water.

At the time of the investigation three H.D.S. plants

Figure 3

belonging to Bethlehem Steel were visited. Their capacities were as follows:

Plant No.	Volume Average	m³/day Maximum	Total Fe mg/l
1.	5 500	5 500	100
2.	24 500	24 500	250
3.	20 000	40 000	
	50 000	70 000	
E.R.P.M.	45 454	90 000	1 500

The plant required at E.R.P.M., judged by existing world standards, had to be relatively large.

What was not known was the amenability of the E.R.P.M. underground water to this treatment process, particularly in the light of the pre-neutralisation step underground.

The following tests with 49 level plug water were therefore conducted at E.R.P.M.:

1. Batch tests trying to simulate a continuous process.
2. Laboratory scale continuous pilot plant runs, feeding underground water at the rate of 125 ml per minute.
3. The conventional water treatment plant at the S.W.V. shaft was converted to the H.D.S. process for the evaluation of the process on a larger scale.

In all three cases positive results were obtained and sludges containing 25 g suspended solids per 100 ml were produced. On the basis of these results, and on basic information provided by Bethlehem Steel, it was decided to use the H.D.S. process and the E.R.P.M. plant was designed.

Description of the E.R.P.M. H.D.S. Plant:

Underground: Four stainless steel pipes feed the water from the plug to a common mixing chamber, where lime slurry is added under gravity from surface to achieve the pre-neutralisation. Very little iron precipitation takes place at this stage. Four pumps are fed from the mixing chamber and the water is pumped via two 356 mm diameter mild steel columns to surface. Each pump, driven by a 4 000 kW motor has a pumping capacity of about 17 000 m³ per day against a head of 1 050 m. In each case two pumps serve one column to surface.

Performance of the H.D.S. plant

On surface (Ref. Fig 3 and 4): Two mixing tanks (A) and four aeration tanks (B) were designed to treat a total flow of 90 000 m³/day. Therefore a 100 per cent stand-by capacity was installed.

The two clarifiers (C) were designed on the basis of sludge settling curves.

The plant dimensions and capacities are given in figure 4.

Considerable process flexibility exists between the mixing tanks and aeration/neutralisation tanks.

Lime Plant: Ground unslaked lime (−2 mm) is supplied by The Northern Lime Co Ltd from its plant at Lime Acres in the Cape Province. The lime arrives at the shaft in special rail tankers, and is pneumatically off-loaded into seven storage and one feed silo. Each silo has a capacity of 200 t.

The lime is slaked in two Omega slakers operating in parallel, to give a milk of lime with a relative density of about 1,05, which is equivalent to a concentration of about 5 g CaO per 100 g suspension. The milk of lime is passed through a settler to eliminate coarse particles which may be carried over from the slakers and which would damage the multi-stage pumps underground. The settler of an old water treatment plant, which is about 50 m from the lime plant, was used for this purpose.

A flow diagram is shown in figure 5. The settler overflow only is piped underground for pre-neutralisation. The lime settler underflow is pumped to the H.D.S. plant. About 10 per cent of the total lime consumption for this process is used for pre-neutralisation underground, the remainder being consumed in the H.D.S. plant.

Performance of the H.D.S. Plant: Pumping at 24

level started during October 1976. The average volume of water pumped and treated per day is about 34 000 m³ (See Fig 6).

The water level behind the plug is monitored by recording the water pressure (Fig. 6) and the pumping rate is varied accordingly. The lime consumption is about 40 t/day for two pumps.

The analyses of underground water and the clarifier overflow are as follows:

ANALYSIS OF WATER

	Directly from the plug at 24 level	O/F of Clarifiers
pH	3,6	7,3
Fe^{2+}	650	Nil
Fe^{3+}	30	Nil
T.D.S.	7 500	5 600
Ppt.S	1 650	15 (ss)

T.D.S. = Total dissolved solids
Ppt.S = Precipitatable solids
SS. = Suspended solids
All figures in mg/l except pH.

There has been an appreciable improvement in the quality of the water obtained at 24 level compared with the water of 49 level which was used originally for experimental purposes.

The clarifier overflow is discharged, under permit from the Government Department of Water Affairs, to the nearest public stream. According to legal requirements the pH of the overflow water must be kept between pH 5,5 and pH 9,5 and the suspended solids level to less than 25 mg/l. Thus far these requirements have been met with ease. Also, the clarifier overflow has not contained soluble iron. Unfortunately there is no simple solution to the fairly high dissolved solids content of the water.

Sludge densities as high as 50 g per 100 ml are readily obtained.

The total capital costs of erection of the plant are as follows:

On surface	R3,2 x 10^6
Underground	R1,9 x 10^6
Plug 49	R0.5 x 10^6
	R5,6 x 10^6

Figure 5

The direct treatment cost of the underground water is about 14 c/m³.

No process, chemical or chemical engineering problems have been encountered at the plant, even during the commissioning period. Rand Mines regard this plant and process as one of the major developments in the mining industry over the past 25 years.[7]

A civil engineering problem was encountered with Clarifier No. 1 where the seals between the floor panels leaked due to bad bonding, but this problem was rectified within a few months.

FUTURE WORK:

☐ One of the investigations which may be carried out in future is the feasibility of mechanically separating the iron hydroxide from the calcium sulphate in the sludge.

☐ One method of H.D.S. sludge disposal, used in Pennsylvania is to deposit the sludge in worked-out underground areas. However, before this can be done it has to be established whether the precipitated iron hydroxide re-dissolves in acidic underground water.

☐ What has also to be determined is where the economic break-even-point between the conventional method and the H.D.S. process lies, taking into account the hydraulic flow of the system and the total underflow tonnage which has to be disposed of.

THE HIGH DENSITY SLUDGE PROCESS
AN IMPROVED TECHNOLOGY FOR HYDROXIDE PRECIPITATION OF HEAVY METALS

by: S. T. Herman
Engineer, Raw Materials and Chemical Processes,
Research Department, Bethlehem Steel Corporation
Bethlehem, Pennsylvania 18016

ABSTRACT

The High-Density Sludge (HDS) process is an improved cold-lime neutralization technique developed by Bethlehem Steel Corporation and originally applied to produce dense sludges in acidic iron-bearing wastewaters such as coal-mine drainage and pickling rinsewaters from steel plant operations. The results of recent laboratory studies are presented that demonstrate the ability of the HDS process to precipitate efficiently, other heavy metals. In laboratory tests with dilute solutions containing copper, cadmium, nickel, lead, and zinc the HDS process was able to reduce all of the soluble metal concentrations to less than 0.1 ppm at a single pH level. This has not been possible with conventional neutralization. Settled sludge concentrations were greater than 20% solids as compared with a normal 1% solids achieved by conventional neutralization techniques.

INTRODUCTION

In the late 1960's Bethlehem Steel's Research Department developed the High-Density Sludge (HDS) process to treat iron-bearing acid mine drainage (AMD) from its bituminous coal mining operations. The process is shown schematically in Figure 1. The main advantage of the HDS process over conventional cold-lime neutralization of AMD is that it can produce a sludge containing up to 50% solids by weight. By comparison, the conventional process generally produces sludges containing 1 to 2% solids by weight. Thus, there is a very substantial reduction in the volume of sludge generated. The HDS process produces a dense sludge by mixing a controlled amount of previously precipitated solids with the an alkaline agent in a separate reactor and using this mixture to neutralize the acidity and precipitate the soluble metals in the wastewater.

In 1979 and 1980 Bethlehem evaluated the potential for using the HDS process to remove both iron and manganese from an AMD discharge at its anthracite mining operations near Tamaqua, Pennsylvania. The bituminous AMD's which Bethlehem had successfully treated with the HDS process contained high ratios of iron to manganese concentrations, e.g., 150 ppm to 200 ppm of iron and 2 to 3 ppm of manganese. The manganese removal was thus enhanced by co-precipitation of relatively large amounts of iron. The anthracite AMD, however, contained only 30 ppm of iron and 13 ppm of manganese. Thus, the beneficial effects of co-precipitation of iron on manganese removal would be much smaller. As part of this program, a small-scale HDS plant was operated on-site for several months. The results of those on-site tests showed that the HDS process reduced the soluble manganese concentrations to levels much lower than expected. A pH of approximately 9 in the HDS process produced manganese removals equivalent to conventional neutralization at a pH of about 10. The HDS process also produced sludge containing up to 50% solids while conventional neutralization sludge contained about 2-3% solids.

In order to study these observations further, additional laboratory studies were carried out with synthetic solutions containing varying amounts of manganese and iron. The results of those studies, shown in Figure 2, demonstrated that: (1) The HDS process precipitated manganese at a lower solution pH than conventional neutralization; (2) the benefits of the co-precipitation of iron on manganese removal in conventional neutralization were carried through and enhanced by the HDS process; and (3) the HDS process produced dense sludges from all of the solutions tested, including one which contained 50 ppm of manganese but no iron. Because of the success seen in these manganese precipitation studies, the test program was expanded to compare the conventional neutralization process and the HDS

process for the precipitation of other heavy metals, including the effects of co-precipitation of iron on both processes.

TEST PROGRAM

Sets of soluble, heavy metal concentrations versus pH were generated for both conventional and HDS neutralization of synthetic solutions containing cadmium, nickel, zinc, copper, and lead. The initial metal concentrations of the seven solutions tested are given in Table 1. The free acidity of all solutions was maintained at 245 ppm, which was sufficient to assure complete solubilization of the metal chloride salts. The effects of co-precipitation of iron were determined by varying the amount of soluble iron in the synthetic wastewaters. All metal analyses were performed by flame and carbon furnace atomic absorption spectrophotometry. It must be emphasized that this study deals only with soluble metal concentrations, not total metal concentrations upon which effluent discharge limitations are based.

CONVENTIONAL NEUTRALIZATION

Test Procedure

The variables in the experiments were the iron to total non-ferrous heavy metal ratio, the concentration of non-ferrous heavy metals, and the pH of the neutralized solution. Conventional neutralization tests were conducted by neutralizing a 25 or 35-liter sample of the synthetic solution with lime slurry. All solutions were aerated during neutralization, and samples were taken at pH 8.0, 8.5, and then every 0.25 pH unit until pH 11.25. After standing for about three hours, the neutralized samples were filtered and the filtrates analyzed for heavy metals. The lime demand and the solids formed upon neutralization were also determined at each pH level. The percent solids at final dilution (concentration of solids after the slurry had settled for 24 hours) were determined at pH 10 for all solutions. Three replicate neutralizations were run for each of the solutions. Figures 3 and 4 and the top plots in Figures 5 through 9 present the results of the conventional neutralization tests. The concentration of soluble iron in the neutralized samples never exceeded the minimum detectable limit of 0.01 ppm and thus is not shown in any of the plots.

Tests with No Iron in Solution

The top plots in Figures 8 and 9 represent the results of neutralizations of solutions containing 50 ppm each and 5 ppm each of the non-ferrous heavy metals but no iron. In all cases the metal concentrations in these two figures are lower than those predicted from solubility data. This is probably due to co-precipitation effects of one metal on another, e.g., the precipitation of copper affects the precipitation of nickel and so on. For the purposes of this test program, the data in the top plots in Figures 8 and 9 were considered the base cases for determining the effects of co-precipitation of iron, and also the effects of the HDS process, on the solubilities of the non-ferrous heavy metals.

Effects of Iron on Metals Precipitation

As expected, the data show that the co-precipitation of iron both reduces the pH necessary to precipitate the non-ferrous heavy metals and reduces the minimum solubilities attainable by hydroxide precipitation. At the higher iron concentrations tested, the amphoteric properties of lead and zinc were eliminated, i.e., the metal hydroxides did not resolubilize as the pH was increased. The data further show that the effects of co-precipitation are more pronounced as the ratio of iron to non-ferrous heavy metals is increased. For example, comparison of the top plots in Figures 5 and 6 show the results of conventional neutralization of two solutions which both contained 50 ppm each of cadmium, nickel, zinc, copper, and lead. The solution in Figure 5 also contained 250 ppm of ferrous iron (iron to total non-ferrous metals ratio of 1:1) while the solution in Figure 6 contained only 25 ppm of ferrous iron (iron to total non-ferrous metals ratio of 0.1:1). Comparison of these plots shows that the higher iron to non-ferrous heavy metals ratio reduced the pH necessary to precipitate the non-ferrous metals and also eliminated the amphoteric properties of the zinc and lead. Similar results can be seen when comparing Figure 3 (iron to total non-ferrous heavy metals ratio of 1:1) with the top portion of Figure 7 (iron to total non-ferrous heavy metals ratio of 10:1). The data also show that, for a given iron to total non-ferrous heavy metals ratio, the beneficial effects of co-precipitation, especially for cadmium and nickel, are more pronounced for lower initial non-ferrous heavy metals concentrations. This can be seen by comparing Figures 3, 4, and the top plot in Figure 5. All of these solutions have an iron to total non-ferrous heavy metal ratio of 1:1. However, as the initial cadmium and nickel concentrations increase, the pH required for their precipitation increases.

Sludge Density

One of the major drawbacks to the use of conventional lime neutralization is the generation of a difficult-to-dewater sludge which contains very low solids concentrations. Table 1 lists the final dilution solids concentrations obtained in the conventional neutralization tests. Although the addition of ferrous iron aided in the removal of the non-ferrous heavy metals, it also greatly increased the volume of sludge generated. For example, the addition of 250 ppm of iron to a solution containing 50 ppm each of cadmium, nickel, zinc, copper, and lead doubled the solids formed upon neutralization.

HIGH-DENSITY SLUDGE NEUTRALIZATION

Test Procedure

All HDS tests were performed in a laboratory-scale unit which was operated 24 hours per day, five days per week at an acid flow rate of approximately 145 ml/min. The process was considered to be in equilibrium when the solids concentration of the recycled sludge reached 10%. Each pH test point in the HDS program was maintained for a minimum of one week. Daily samples of the raw acid solution and thickener effluent were taken for soluble heavy metals analysis. The solids concentration in the thickener underflow and the lime demand were also determined daily. Due to time constraints, only five of the synthetic solutions tested in the conventional neutralization study were tested in the HDS system.

Test Results

The results of the HDS neutralization studies are presented in the bottom plots in Figures 5 through 9. The concentration of soluble iron in the thickener effluent never exceeded the minimum detectable limit of 0.01 ppm and thus is not shown in any of the plots. Several conclusions can be drawn by comparing the HDS neutralization curves with those for conventional neutralization of the same solutions.

- At any given pH, the HDS process produced lower soluble cadmium and nickel concentrations than conventional neutralization.
- For the amphoteric metal hydroxides (zinc and lead), the HDS process produced minimum solubilities at approximately the same pH level as conventional neutralization. However, even without the benefit of the co-precipitation

of iron, the HDS process reduced the amount of lead and zinc which resolubilized when pH levels were increased above the minimum solubility point.

- There was only one case, lead in solution 2 (Figure 6), in which the HDS process failed to produce minimum soluble metal concentrations as low or lower than those achieved by conventional neutralization.

- For those solutions which contained no iron, the HDS process was able to reduce all the soluble heavy metal concentrations to less than 0.1 ppm in the pH range 10.1 to 10.3. Conventional neutralization techniques were unable to reduce the soluble metal concentrations of all of the metals to less than 0.1 ppm.

HDS Treatment With Separately Generated Iron Sludge

The HDS testing of solution 7, which contained 5 ppm of each of the non-ferrous heavy metals but no iron, was conducted in a different manner from the other HDS tests. Since solution 7 generated very few solids upon neutralization, it would have taken an extremely long time to generate enough sludge to recycle. A dense sludge was generated by using the HDS process to neutralize a solution containing 500 ppm of ferrous iron. This sludge was then used as the recycle slurry to test the removal of non-ferrous heavy metals from solution 2. The results of this test are shown in the bottom plot of Figure 9. This was the only test in which cadmium was removed at a lower pH than nickel. Also, while the average metal concentrations were reduced to low levels at relatively low pH values, the individual daily analytical results were the most widely scattered of all the tests. Although time constraints did not permit additional experimentation, this variation of the HDS process could be very useful for treating solutions containing low initial concentrations of soluble heavy metals.

Sludge Density

The HDS process produced dense sludges for all five solutions tested. Table 1 lists the sludge densities produced from each solution by conventional and HDS neutralization. It is obvious that the HDS process greatly reduces sludge disposal problems, especially if co-precipitation of iron is utilized to obtain minimum heavy metal concentrations. For example, conventional neutralization of 500 gpm of solution 1 would produce about 55 gallons per minute of sludge containing 0.8 % solids. The HDS process would produce 1.2 gpm of sludge containing 30 % solids by weight.

Lime Requirements

Although the HDS process removes metals at a lower pH value than conventional neutralization, the lime demands for both processes are the same for identical metals removal efficiencies.

The work described in this paper was not funded by the U.S. Environmental Protection Agency and therefore the contents do not necessarily reflect the views of the Agency and no official endorsement should be inferred.

High-density sludge process—an improved technology for treating acidic metal-bearing wastewaters

Many wastewaters from steel plant and mining operations have traditionally been difficult to treat effectively prior to approved discharge into public waters. The reason: conventional neutralization processes that treat acidic metal-bearing wastewaters produce very dilute sludges and are not efficient in precipitating mixtures of dissolved heavy metals. Bethlehem International Engineering Corporation is authorized to license a high-density sludge process that does this job better and more economically than conventional processes.

Also applicable to the treatment of acid mine drainage, the process may reduce costs to build and operate a treatment facility. This economy results from: (1) a substantially higher-density sludge, (2) improved slurry filterability; (3) improved reduction of metal concentrations, and (4), in some cases, the smaller size of the clarifier/thickener required.

The process is in operation at three Bethlehem Steel Corporation plants, five Bethlehem Mines Corporation bituminous coal mines, and a South African gold mine. A new facility for a Bethlehem Mines Corporation anthracite coal mine is under construction. (See Table, Figure 3, on reverse side of this sheet.)

This technology is now available for licensing from Bethlehem International Engineering Corporation.

Figure 1: Full-scale plant in operation at Bethlehem Mine's Mine 38, Cambria, Pa.

Figure 2: Lime neutralization of pickling wastewaters, two methods.

Technical description of High-Density Sludge Process
This is a neutralization technique which, unlike conventional processes, produces a dense sludge while improving the efficiency of precipitating heavy metals from solution.

Applications:
Federal, state, and local environmental control regulations require removal of most heavy metals from wastewater prior to discharge to public waters. The process is used to precipitate heavy metals from wastewaters while producing a dense sludge which is more easily disposed of than that produced by conventional neutralization processes. The process is applicable to most acidic wastewaters containing soluble heavy metals. For example:

- ☐ Acid mine drainage
- ☐ Steel plant pickling rinse waters
- ☐ Blowdown streams from steel plant recirculating water systems.

Advantages to users:
Compared with conventional neutralization techniques, the high-density sludge process:

1. Reduces the sludge volume by a factor of 10-50
2. Improves the slurry filterability
3. Reduces metal concentrations to levels below the published theoretical solubilities at a given pH
4. In some cases, reduces size of clarifier/thickener

Due to the above advantages, the process reduces the capital and operating cost for facilities to handle, store, and dispose of the sludge generated. For some solutions, the reduced pH at which the metals are precipitated can eliminate the need for a final pH adjustment of the clarified wastewater.

Installation requirements:
Construction of a high-density sludge facility usually requires less real estate and major capital equipment for sludge disposal when compared with conventional neutralization techniques. A second, small reactor tank plus slurry recycle pumps are also required for the high-density sludge process.

Maintenance requirements:
Similar to those for a conventional neutralization system.

TREATMENT OF ACID AND METAL-BEARING WASTEWATERS BY THE HIGH-DENSITY SLUDGE PROCESS

By F. M. TEMMEL

Manager, Metallurgical and Chemical Process Research
Homer Research Laboratories
Bethlehem Steel Corporation

ABSTRACT

BETHLEHEM STEEL HAS for many years studied neutralization methods for the treatment of acid wastewaters from mining and steel processing operations. This research has resulted in the development of a high-density sludge (HDS) process to treat acidic, metal-bearing wastewaters. The sludge generated during treatment amounts to as little as 1/50th of the volume produced by conventional neutralization.

The significant operating parameters which affect sludge density and plant design in this new treatment method are:

- Ferrous to ferric iron ratio
- Ratio of solids recirculated to solids precipitated
- Point of alkalinity addition
- Neutralization pH
- Detention time in reaction tanks

Prepared for presentation at San Francisco Regional Technical Meeting of American Iron and Steel Institute, November 18, 1971.
Copyright © 1971, American Iron and Steel Institute

To date Bethlehem Steel has in operation three HDS plants designed to treat 11,000,000 gallons a day of acidic iron-bearing wastewaters, two treating acid mine water and one treating steel plant acid rinsewaters. One additional plant for 4.0 million gallons a day of acid mine water is in the construction stage and another for 2.0 million gal/day of acid rinsewater is in the design stage.

INTRODUCTION

Many technical articles have been written about conventional lime neutralization processes for the treatment of acid wastewaters from mining and steel processing operations. These conventional processes produce voluminous, gelatinous sludges that contain only 1 to 2 per cent solids and are not economically amenable to further dewatering by filtration or centrifugation. This limitation has been and still is the dilemna of conventional neutralization. Sufficient land areas in most cases are not available for the large volumes of sludge produced by conventional neutralization. Today there are about 200 treatment plants in Pennsylvania alone using one form or another of conventional neutralization for treating acid mine waters, and the resultant sludge handling and accumulation problems are staggering. It is in this problem area that Bethlehem Steel developed a treatment method which generates a sludge amounting to as little as 1/50th of the volume produced by conventional neutralization. This improved neutralization method is called the High-Density Sludge (HDS) Process.

In Pennsylvania it has been estimated that approximately 2 billion gal/day of acid mine waters from coal mines are being discharged to clean streams, i.e., 200 million gal/day (834,000 tons/day) from active mines and 1.8 billion gal/day (7,500,000 tons/day) from inactive and abandoned mines. The sulfuric acid and iron contents of waters from the active mines are estimated to be 460 and 180 tons/day, respectively. If we assume that all of Pennsylvania's acid mine water were neutralized by conventional lime treatment, about 100 million gal/day of sludge would be generated. In contrast, if this same volume of acid mine waters were treated via Bethlehem's High-Density Sludge Process, only 4 million gal/day of sludge would be produced. This hypothetical illustration clearly indicates

the need for a neutralization process which would produce a smaller quantity of sludge for disposal.

The acid mine water discharges from Bethlehem's Cambria Division alone total approximately 11 million gal/day. The treatment of these waters by conventional neutralization would produce about 500,000 gal/day of sludge, whereas treatment with the High-Density Sludge process produces only about 20,000 gal/day of sludge. For this reason Bethlehem is installing facilities for treating these waters by the High-Density Sludge process.

PROCESS DESCRIPTION

The primary differences between the High-Density Sludge process and conventional neutralization can be seen in Fig. 1. Conventional lime neutralization consists of:

- Mixing high-calcium or dolomitic lime with water to produce a lime slurry
- Neutralizing the acid wastewater with the lime slurry at

Fig. 1—Lime Neutralization of pickling wastewaters.

ambient temperature in a stirred reaction tank, either with or without aeration

- Settling the solids precipitated from the acid wastewater in a clarifier, thickener, or settling pond
- Discharging the neutral, clarified overflow and disposing of the voluminous, gelatinous sludge *somewhere!*

As shown in the lower half of Fig. 1, neutralization by the HDS process differs from conventional neutralization in that provisions are made for:

- Recycling a controlled volume of the settled sludge
- Mixing the recycled sludge with lime slurry in a reaction tank prior to the neutralization and separation steps.

As shown, the volume of sludge generated using this process is only about 1/25th that which would be generated using conventional neutralization. Actually, sludge volumes from the HDS process vary from 1/15th to 1/50th, depending on actual controlled process conditions.

Operating Parameters

The significant operating parameters which affect sludge density and plant design are:

- Ferrous to ferric iron ratio of acid wastewater
- Ratio of solids recirculated to solids precipitated
- Point of alkalinity addition
- Neutralization pH
- Detention time in reaction tanks "A" and "B"

Ferrous to Ferric Iron Ratio. All test work showed that the ratio of ferrous to ferric iron in the acid wastewater to be treated had a direct effect on the maximum concentration of settled solids that could be produced by this process.

The effect of ferrous iron content on settled sludge density is shown in Fig. 2. Little effect on sludge density was found when the ferrous content of the total iron was less than about 70 per cent; however, at ferrous iron percentages of greater than 70 per cent a very significant increase in sludge density was noted—up to about 50 per cent solids for 100 per cent ferrous iron.

Ratio of Solids Recirculated to Solids Precipitated. The ratio of solids recirculated within the system to the solids precipi-

Fig. 2—Effect of ferrous iron concentration on sludge density.

tated from the acid mine water by the neutralization reaction was found to be of primary importance in controlling sludge density. The effect of this ratio on sludge density for the ferric acid mine water from Mine 31 and the ferrous acid mine water from Mine 32 is shown in Fig. 3. The two curves show that the solids concentration increased rapidly as the recirculation ratio was increased to 20:1, the rate of increase in concentration decreased in the ratio range of about 20:1 to 30:1, and the percentage increase in concentration was relatively small in the ratio range of 30:1 to 80:1. The optimum range was 25:1 to 30:1, which is consistent with good process control, the production of near-maximum sludge densities, and minimum area requirements for sludge settling and thickening. It

Fig. 3—Effect of solids recycle ratio on sludge density.

is of interest to note that this optimum solids recirculation ratio range was the same for both ferrous and ferric waters.

Point of Alkalinity Addition. The HDS process gains its ability to produce maximum-density sludges from the practice of mixing lime slurry with recycle slurry before reacting the high pH mixture with acid mine water. This is of primary importance. In a short-term test it was shown that mixing lime slurry, recycle slurry, and acid mine water in a single reaction tank resulted in process failure. Similarly poor results were obtained when the acid mine water and recycle slurry were mixed in the neutralization reactor.

Neutralization pH. The neutralization pH was found to have a significant effect on the physical characteristics of the neutralized slurry and on the thickener area required for sludge settling.

- The optimum pH range from overall process considerations was 7.2-7.7. Within this range, the oxidation rate of the ferrous iron was satisfactory, sludges of maximum density were produced, and thickener area requirements were at a minimum.

- A neutralization pH range of 6.0-6.5 reduced the alkalinity requirements, but the oxidation and precipitation rates of the iron were too slow for practical consideration in sizing the neutralization reactor.
- A neutralization pH range of 8.2-8.7 reduced the turbidity of the clarified effluent but decreased the settled solids concentration from 35 per cent to 20 per cent and increased the settling area requirements by a factor of 1.6.
- A pH range of 9.0-9.5 resulted in the production of a rubbery sludge that could only be pumped with difficulty and increased the torque on the thickener rakes to the extent that the rakes became inoperative.

Detention Time in the Reaction Tanks. The results of laboratory tests on the effect of detention time on the overall process showed that a detention time of one minute in the sludge reaction tank was sufficient to produce and maintain sludges of maximum density, and that a detention time of ten minutes in the neutralization-oxidation tank ensured oxidation and precipitation of the ferrous iron from the acid mine drainage at any pH value above 7.2. A maximum detention time of one minute in the sludge reaction tank is considered to be a good design number for an HDS system, but detention time in the neutralization tank is a function of both the initial ferrous iron concentration and the neutralization pH.

DEMONSTRATION PLANT

A flow diagram of the 1 million gal/day HDS Demonstration Plant at Mine 32 near Ebensburg, PA is shown in Fig. 4. This plant was designed from data obtained from laboratory and pilot-plant studies. The HDS plants studied in the laboratory and pilot plant are shown in Figs. 5 and 6, respectively. The basic equipment in this treatment system consists of a lime storage bin, lime slaker, sludge reactor, neutralization reactor and thickener. Fig. 7 shows the Demonstration Plant with its lime storage bin, sludge reactor, neutralization reactor, and a 60-ft thickener. The plant operation, shown in Fig. 4, is as follows:

- The acid mine water is pumped from the mine to the neutralization reactor (Reactor "B").

Fig. 4—Flow diagram: HDS demonstration plant at Coal Mine 32.

Fig. 5—Laboratory high density sludge plant.

Fig. 6—High density sludge pilot plant.

Fig. 7—High density sludge demonstration plant.

- The lime slurry is pumped to the sludge reactor (Reactor "A"), where it is mixed with sludge recycled from the thickener underflow.
- This sludge mixture flows by gravity from reactor "A" to reactor "B", where it is mixed with the acid mine water and aerated. Here the pH is controlled at about 7.5, the ferrous iron is oxidized to the ferric form, and the iron is precipitated as ferric hydroxide.
- The neutralized slurry then flows by gravity from reactor "B" to a thickener, where it settles to about 35 per cent solids.
- The thickener overflow is discharged to public waters, and the sludge produced is discharged once a day through a borehole to an abandoned section of the mine.

FULL-SCALE PLANTS

The demonstration plant at Mine 32 was redesigned and enlarged to treat 6.2 million gal/day. This plant was put into operation in February 1971. Fig. 8 shows the full-scale HDS plant at Bethlehem's Mine 77 after startup in November 1969. This plant was designed to treat an estimated 1.8 million gal/day based on a planned expansion of Mine 77; at present it treats 0.8 million gal/day of acid mine water. In addition to these two operating plants, a third plant capable of treating 4.0 million gal/day of acid mine water is being constructed now with startup scheduled for October 1971.

Having successfully demonstrated the feasibility of the HDS process for treating acid mine waters we decided to study the applicability of this new method to treating acid rinsewaters from steelmaking operations. The transition was not obvious since the makeup of the two waters is somewhat different. Whereas iron and sulfuric acid are the major components in acid mine water, the acidic rinsewaters produced in our operating steel plants contain other metals and/or mineral acidity which also require treatment. For example, acidic rinsewaters from continuous galvanizing operations contain zinc and sulfuric acid; rinsewaters from continuous picklers contain iron and hydrochloric acid and rinsewaters from a typical wire mill

Fig. 8—Full-scale high density sludge plant treating acid mine water.

operation contain iron and zinc as well as dilute sulfuric and hydrochloric acid.

Our first effort to extend the HDS process capability was based on laboratory tests using feed with the composition of rinsewater from a typical hydrochloric acid pickling operation. After successfully demonstrating the process at this level, a pilot program was conducted at our Lackawanna plant to get design data for a full-scale plant to treat acidic rinsewaters from the continuous picklers and galvanizers. Upon completion of the test, a 3 million gal/day HDS plant was designed and built to treat these acidic rinse waters. The full-scale facility was started up at Bethlehem's Lackawanna Plant in December 1970. The flow diagram, Fig. 9, for this system is similar to the flow diagram for the Demonstration Plant at Mine 32 shown in Fig. 4, except that the excess sludge from this system is disposed of by trucking to a dump. The HDS plant at Lackawanna was designed for treating acid wastewater containing 440 ppm Fe, 40 ppm Zn, 600 ppm Cl, 1370 ppm SO_4, and 2280 ppm total acidity as $CaCO_3$, and producing an effluent that will meet the New York State water quality criteria. These criteria are pH 6.5 to 8.5, less than 15 ppm Fe, and less than

Fig. 9—Flow diagram: HDS plant at Lackawanna Steel Plant.

40 ppm suspended solids. Because the acid wastewater flow and composition vary drastically in the Lackawanna HDS plant, more sophisticated controls are required for maintaining the pH in reactor "B" than the controls in HDS plants for treating acid mine waters. The control system installed consists of measuring conductivity and flow of the acid wastewater in a feed-forward circuit and a pH feedback circuit. Since January 1971 the Lackawanna HDS plant has been satisfactorily treating 800 to 1900 gpm of acidic wastewater. During the month of June 1971, the most recent month for which operating data are available, the continuous picklers operated 151 turns and the galvanizing mill ran 55 turns. The average wastewater volume treated was 1700 gpm; the wastewater contained from 150 to 695 ppm Fe and from 340 to 2330 ppm total acidity as $CaCO_3$. Treated effluent averaged 13 ppm Fe, 27 ppm total suspended solids, and pH of 8.2. By using the HDS principle, the volume of sludge to be disposed of was only about 10,000 gpd with a 30 per cent solids concentration instead of the 300,000 gpd of sludge that would have been produced from a conventional neutralization plant. The estimated cost to treat 1,000 gallons of acid rinse waters is 20 cents; of this amount, 10 cents is for labor and supervision and five cents is for

chemical lime. Fig. 10 shows the outside of the No. 7 Water Treatment Station at Lackawanna, which consists of the HDS plant and an ultrahigh-rate filtration plant for treating oily wastewaters from the cold reduction mills. The thickener in

Fig. 10—Full-scale high density sludge plant treating steel plant acid rinse waters.

Fig. 11—Laboratory facilities at Water Treatment Station No. 7.

the foreground is part of the HDS system. Laboratory facilities at this location are shown in Fig. 11.

A 2-million gal/day HDS plant is presently being engineered to treat acid wastewaters from the Wire Mill at our Johnstown Plant. As shown in Fig. 12 the system is similar to the one at Lackawanna, except that the flow is split and sent to two parallel treatment facilities after exiting from reactor "A". The parallel network was selected primarily because of space limitations; however, it offers the added advantage of at least a 50 per cent operation in the event of equipment failure.

Fig. 12—Flow diagram: HDS plant at Johnstown steel plant.

SUMMARY

In summary, the high-density sludge process proved its effectiveness in comparison to alternate methods of treatment and has been applied full-scale not only to all of our acid mine water discharges at the Cambria Division of Bethlehem Mines but also to the 3 million gal/day acid rinsewaters from

our continuous descaling lines at our Lackawanna Plant. Finally, we are in the detailed engineering stage of an HDS plant for handling the 2 million gal/day acid wastewaters from our wire mill descaling operations at Johnstown.

To date, Bethlehem has spent approximately $4,000,000 in HDS plants. As shown below, the plants have the capacity to treat 17,000,000 gal/day of acidic, iron-bearing wastewaters.

BETHLEHEM STEEL CORPORATION HDS PLANTS

Location	*Design Capacity*	*Startup Date*
Johnstown	2,000,000 gpd	At Engineering Stage
Lackawanna	3,000,000	December, 1970
Cambria Division Mines		
Mine 31	4,000,000	October, 1971
Mine 32	6,200,000	February, 1971
Mine 77	1,800,000	November, 1969
Total	17,000,000 gpd	

The total sludge volume that will be produced by treating 17,000,000 gal/day wastewaters will be 43,000 gal/day instead of the 990,000 gal/day if conventional neutralization were used.

Having identified several HDS plant installations and provided a description of their operation, performance, and cost, it remains to summarize some of the operating and design parameters to identify several innovations. Some of the problems are also described, as well as measures used, to overcome them in operating plants.

1. Bethlehem Mines Corp, Panther Valley Division

This large HDS plant is designed to treat 12,000 gpm or 65,000 m^3/d minewater pumped from a deep open pit anthracite coal mine. The interesting aspect is that pH is 6.8, but the minewater contains a ferrous iron level of 30 ppm and 13 ppm Mn, which is a low Fe^{2+} to Mn ratio for HDS. HERMAN and KORB (?), in describing the pilot testwork, found that:

- Aeration of AMD prior to neutralization reduces lime demand by abut 40%. This requires one 50HP Fuller Corp. wisp blower to reduce the CO_2 level in this water by aeration at 600 scfm, discharging below two 25HP turbine mixers in the aerator reactor.

$$H_2CO_3 = HCO_3^- + H^+$$
$$H_2CO_3 = H_2O + CO_2$$

  By a vigorous aeration, the CO_2 is blown off, thereby reducing bicarbonate levels according to the above equations.

  Aeration can increase the pH of the feed from 6.3 to 7.2-7.3.

  The way to test whether pre-aeration will reduce lime consumption is to measure the pH during aeration in the laboratory. If the pH rises, this indicates that there will be a saving. Also, the amount of lime required to achieve a given pH with and without aeration can be measured in the laboratory.

- Aeration prior to lime addition reduces the solids precipitated at pH 10 by 35%.

- After aeration, the water is agitated in B reactor by 300 cfm air introduced under two 25HP turbine mixers to oxidize ferrous to ferric iron. The lime slurry with thickener underflow sludge are mixed in A reactor using a 7.5 HP agitator and pumped to B reactor to be mixed with the aerated minewater.

- Neutralized AMD is pumped to a 250 foot (76m) diameter thickener which was constructed by modifying an existing 200 foot Ø thickener to save cost. A 9 foot side water depth was maintained. The steel walled thickener has a concrete floor.

BETHLEHEM MINES CORPORATION

AERATION REDUCES CO_2 LEVEL IN WATER

HDS CLARIFIER

B REACTOR - NOTE BAFFLES

- Submersible centrifugal pumps are utilized to recycle sludge from the thickener to a reactor. Thickener effluent is used to slake the high-calcium pebble lime.

- No polymer use is required.

- Even at the approximate ratio of Fe^{2+}:Mn of about 2.5:1, the HDS process reduces the volume of sludge to only 10% of that from conventional precipitation.

  The Panther Valley plant was operated to yield a 34% solids density sludge. The sludge is pumped to the pit at SG 1.15-1.25 through a 5500' pipeline of 6" Ø. It would be possible to achieve densities up to 50% solids at which it is like a paste and impractical to pump.

  Using conventional neutralization, about 20 m^3 of sludge would be generated for each 1000 m^3 treated or about 1300 m^3/d at the design capacity. This would fill a pond 100m x 100m x 3m deep every month, and the sludge would not be amenable to further dewatering.

- Using conventional precipitation if there is not excess iron to coprecipitate manganese, the latter readily goes back into solution if the pH is dropped below pH 9.

- Lime demand to reduce Mn concentration to less than 1 ppm was the same by HDS and conventional precipitation. However, HDS was able to reduce Mn to less than 1 ppm at pH 9 as opposed to pH 10 by conventional neutralization.

- pH control is smoother using HDS.

- Calcium carbonate scale formation occurred in the conventional neutralization process but not in the HDS test as $CaCO_3$ is forced to precipitate in B reactor sludges.

- The minewater temperature remains at 54°F yearround, so there is no temperature effect on the process.

- The Panther Valley lime addition is controlled by a Leeds & Northrop pH meter in reactor B that controls the lime slaker flowrate to maintain pH 8.9 in Reactor B. Ultrasonic cleaners for the pH probe were not successful at this plant.

- All lime slurry addition is by gravity flow.

- The lime slaker was supplied by:

BIF CORP.
Unit of General Signal Corp.

- Polyethylene piping used for water and sludge disposal is found to be very resistent to scale and corrosion as there is no easy surface for scale forming bacteria to attach themselves to.

- The HDS plant now operates without the addition of flocculant, said to be a characteristic of this process when operated properly.

2. Kromdraai Coal Mine HDS

An HDS plant was installed in the early 1970's at the restored Coronation Colliery site at Kromdraai, near Witbank, Transvaal to treat 14,000 m^3/d acid mine water pumped from underground.

Conventional lime neutralization and clarification yielded the following results in tests described by BOSMAN (1974).

	Influent	Effluent
pH	2.7	7.5
Acidity $CaCO_3$:	1000	
Conductivity/m	18.0×10^6	
TDS mg/l	1750	1800
Fe^{2+} mg/l	0-140	1
Fe^{3+} mg/l	30-200	30
Fe_T mg/l	175	

	Influent	Effluent
Al mg/l	90	1
Ca mg/l	30	450
Mg mg/l	10	20
Na mg/l	5	
K mg/l	3	
$SO_4^=$ mg/l	1150	
Cl^- mg/l	5	
Suspended Solids		60

The Kromdraai HDS plant was visited in December, 1983, and several observations were made:

- Product water after HDS neutralization is now used at 93AD army headquarters nearby for lavatories and showers. An initial attempt to use the water as a potable source had the army "on the trot," due to its high $SO_4^=$ content.

- Lime consumption to neutralize 14,000 m^3/d AMD at pH 2.2-2.4 amounted to 750 tpm, i.e., 2.5 Kg lime per m^3 (2.5g $Ca(OH)_2$/l).

- The HDS operation has been run at between 15% and 25% solids in the sludge and occasionally up to 34% solids. This is possibly because of the low ferrous to ferric ratio which is an important parameter for sludge density although, since there is more than ample sludge storage capacity at the site, there has been no need to optimize the process. A higher sludge density would only serve to increase pumping problems. The sludge disposal ponds are located 5500 feet from the plantsite.

The equipment installed at the plant is as follows:

Lime Silo	1.5 HP Vibrator Feeder
Lime Slaker	
Air Compressor	Godfrey
Compressor Cooling System	60HP
Premix Tank	
Reactor-Aerator	60HP Moyno Pump
Thickener-Clarifier	Est. 150'Ø

Valves and piping are shown on the attached sketch.

- Suspended solids in the thickener overflow from the full scale plant is much lower than the 60 ppm s/s in the pilot plant.

:AAI COAL MINE HDS PLANT

HIGH DENSITY SLUDGE IS STABLE

HDS PLANT
OLD CORONATION MINE, KROMDRAAI

- The plant is operated and maintained by one operator and two unskilled assistants.

- The original plant was installed with an underground 3"Ø line to feed slaked lime slurry from the lime slaker tank to the sludge premix tank. The line diameter proved too large resulting in inadequate flow velocity and the settling out of solids resulting in the line clogging. The problem was solved by installing a 1½"Ø flexible plastic line above ground level to transfer lime slurry to the premix tank.

- Although designed for automatic control, it has proven more practical to operate the plant manually.

- Sludge settles and dries to a very stable material. It is very low density but stable enough to easily support a man's weight and is suitable for permanent restoration of the ponds upon completion.

- According to BOSMAN (1974), the thickener is designed for a rising velocity of 0.4 m/h compared with 0.57 m/h in the pilot plant which yielded 60 mg suspended solids/l. This compares with Bethlehem Steel Corp. effluents with less than 7 or 8 ppm iron at a rising velocity of 0.7 m/h.

- The operator recommends that flanged sludge recycle lines be installed in any new plant to facilitate unclogging as needed.

- No scale problems are experienced, probably because of the low $CaSO_4$ concentration in the water, and low carbonates.

3. Noranda Mines Ltd., Waite-Amulet, Quebec

This operation is designed to treat 4320 m^3/d (660 lgpm) acid mine drainage from 8,000,000 tons sulfide tailings in a 100 acre pile and mine drainage from a restored zinc mining site near Noranda Quebec. This plant was designed and constructed after examining all the HDS plants then operating in Canada. It therefore represents the best of Canadian experience.

- Plant Startup: 1983.

- Water Treatment (Average for 1984):

	Influent	Treated	Polished and Treated

- Capital Cost: Estimated C$1.7 million (1983).

- Operating Cost (1983 Projection):

Lime	C$231,000	C$0.10/m³
Polymer	C$ 12,000	C$0.005/m³
Labor	C$ 55,000	C$0.023/m³
Power	C$ 32,000	C$0.0135/m³
Total	C$330,000	C$0.142/m³

- Water treatment costs were significantly reduced by reducing the watershed that drains into the affected area from 1000 acres to 313 acres through various diversion projects. Through successful revegetation of the sulfide rich dumps, an attempt has been made to reduce the rate of acid and dissolved metal generation.

- Being located in a cold climate, the Waite-Amulet treatment plant, including thickeners, is installed indoors in a building measuring 42' wide x 65' long x 34', i.e., 2730 ft².

- To accomplish the compact plant, a lamella platepack thickener is used inside a small indoor indoor clarifier tank.

- The Waite-Amulet system includes:

  - Acidic water retention pond--adequate for one in 25 year rainfall containment; 252 acre-feet.

- Water treatment plant for 660 Igpm allowing 20% margin over the required one in ten year maximum inflow to be treated.

- Polishing pond for treated effluent.

- Three division sludge storage and dewatering ponds with porous sand floors.

- Provision to add lime at the decant point to any excess effluent over and above the capacity of the treatment plant that might have to be released in an emergency to Lake Default.

° The HDS plant consists of the following:

- Lime storage; 60 ton skirt supported lime silo outdoors.

- Lime slurry preparation system 1/3 HP Lightin mixer, 3-4 minute retention, deep vortex mixing, Schutte and Koerting water jet eductor, lime slurry pump.

- Lime-recycle sludge mixing tank; Prochem 10HP mixer.

- Two neutralization reactors, each 15,200 I gallons mixed by Prochem agitators with baffles and air lances at 7 psi.

- One 26'Ø x 20', 60,000 I gal. thickener fitted with an Axel Johnson LGS-T3200-55 Lamella Plate Pack. The thickener has a rake mechanism to bring sludge to a central discharge point.

- 12'Ø x 15'6" h. sludge storage tank, 10,400 I gal.

- 400 cfm blower system 15 psi.

° The HDS plant at Waite-Amulet was required to reduce the volume of precipitate sludges generated by treating the AMD. A 3.3 active acre lagoon would have been adequate storage for 3-6 months sludge generated by conventional neutralization.

° The HDS plant was designed by Noranda in conjunction with P. W. Shipley of P. W. Shipley Associates.

° Cost of lime at the Noranda, Quebec site is $144/st in bulk. Lime demand in 1984 was 12 lbs. per 1,000 I gallon or 1.2 Kg lime/m^3.

- The Waite-Amulet HDS plant is designed to be completely automatic. Controls and sensors place the plant on hold when there is a shutdown and indicate a problem at at the Horne Division Control Room.

- The plant is operated at a steady flow of 800 lgpm provided by a pump at the pond. To achieve a trouble free operation the plant is operated at a steady flow. When there is inadequate water in the pond to achieve this flowrate, the plant shuts itself off.

- Flowrate is measured using an ultrasonic device on a Parshall flume, which measures flow and solids density of the underflow, made by:

  MARIG, INC.
  #230, 3300 Boulevard Cavendish
  Montreal, Quebec H4B 2M8
  (514) 487-1024
  Telex: 055-66305

- For the automated plant, hydrated lime was selected over quicklime to avoid the need for a slaker or storage reservoir and to minimize operator and maintenance requirements. At the time of the visit, NORANDA had not yet reached a final conclusion about quicklime vs. hydrated lime relative merits.

- Lime discharge from the feeder is connected to a totally enclosed polyethylene mixing tank. Makeup water is piped through the lid of the tank at a constant flow rate to produce 30% slurry at maximum lime demand of 20 lbs/minute. The water nozzle is positioned to induce a deep vortex in conjunction with a 1/3 Greey-Lightnin mixer. Lime flowing into the vortex is carried to the downdraft impeller where it mixes instantaneously to produce a lime slurry. The mixing tank has a 3-4 minute retention time to give a fast response to the control loop.

- A submerged overflow from the lime mixing tank flows into an enclosed funnel which discharges to the suction port of a "Schutte and Koerting" type 264 carbon steel water jet eductor. Even though a 1 1/2" water jet eductor can handle 5/16" particles, the submerged overflow at the mixing tank prevents any non-dissolved lime from reporting to the eductor. The system delivers 8 gpm of 30% lime slurry against 15 psi back pressure. The system has proven itself to be simple and reliable to convey a lime slurry for short distances and with small lifts. This system elevates the slurry 22 feet to the delivery point.

By enclosing the rotary feeder discharge, the lime mixing tank, and the eductor funnel, a slight negative pressure is created in the lime system and the escape of lime dust is minimal. This system is installed at both Geco Division and Waite-Amulet with successful results.

- Sludge-Lime Mixing

  Sludge is recycled to the lime-slurry mixer fitted with a Prochem 10 HP Type 640 ft. 10 agitator at 44.6 RPM. The baffled sludge recycle tank measures 12'Ø x 6' high with 3200 Igal. (14.5m^3) storage capacity, designed for 15 minutes retention. This modifies the sludge solids from a fluffy slime to an almost particulate texture.

- Neutralization Reactor Tanks

  Two reactors, each 15,200 I gallons (69 m^3 each), are sized for 23 minutes residence time not counting sludge recycle and 20 minutes including sludge recyle, which indicates 27 m^3/h sludge recycled.

  The tanks are of mild steel with mixing and discharge baffles and a cone bottom discharge. All wetted parts are coal-tar-epoxy coated. Agitation uses Prochem agitators, one in each tank, and 7 psi aeration.

- Air was to be injected in the primary neutralization reactor at 15 psi and 400 scfm (0.6 scfm/Igpm) to convert ferrous to ferric. The idea was to minimize gypsum scaling by keeping an accelerated motion of the particles while they formed.

  During the visit, however, air was injected at 7 psi via four removable air lines per tank inserted below the Prochem mixers.

  To prevent spillage, and to contain any foam that might occur, the tanks have a 2.5' freeboard.

Polymer System

Liquid polymer is used which is much simpler to use than a dry polymer makeup system. Liquid polymer systems are currently in use at two INCO plants and at NORANDA MINES LTD., Geco Division.

Alchem HC35 flocculant was in use at the time of the visit, although Alchem 8C26, 8C35 and 87079 had been tested.

Liquid polymer was to be introduced via a variable speed "Liquid Metronic" model D73 pump. However, during the visit to the actual plant, a Stanco Polyblend Bradley Illinois polymer pump was in use. This pump was reputedly invented at NORANDA's Geco Division. The flocculant is mixed into thickener of water bleedstream via a T static mixer and then passes through a 300' clear plasic 1"Ø pipe acting as an aging coil before being injected into a 5gpm stream for a second dilution which carries it to the delivery point which is achieved by inserting the end of the diluted flocculant solution into the overflow

upcomer at the discharge of the second neutralizing tank allowing flocculant to disperse in the water as it cascades down the trough leading to the clarifier.

The use of flash mixers for flocculant mixing was dispensed with after NORANDA staff visited several installations using the static mixers or propeller mixers were found to have been removed.

Solid/Liquid Separation

NORANDA tests indicated a clarifier rate at 0.2-0.5 lgpm/ft^2 (0.54-1.36 m/h). To enable the clarifier to operate indoors a lamella clarifier was selected. Conventional thickeners operated in Canada alsoexperience interference due to surface currents on the sludge blanket. A circular thickener 26 ft Ø x 20 is installed and fitted with an Axel-Johnson LGS-T3200-55 Lamella plate pack and a rake mechanism to bring sludge to the central discharge point.

Sludge level is detected using a Sensall device supplied by:

NATIONAL SONICS DIVISION
Sensall Control
Xertex Corporation
Hauppauge, NY 11787

The Lamella plate packs are made by:

AXEL-JOHNSON LTD.
Montreal

Sludge Handling

Based on experience at NORANDA, Mattabi Division, where the original Moyno pump was replaced by an SRL type centrifugal pump, the latter was installed at Waite-Amulet. Positive displacement pumps normally prefered for this type of job require so much maintenance that the benefits do not offset the greater reliability of SRL centrifugal pumps. floc breakage can be overcome by a little extra flocculant dosage.

At COMINCO's Kimberly, B.C., plant two SRL Allis Chalmers pumps are installed, each capable of recycling 850 lgpm sludge. At Kimberly the pumps are fitted with DC variable speed motors, and one pump operates at a time. Cominco reportedly initially experienced problems with constantly changing polymer dosage requirements created by the solid mass flow not being uniform. The RPM of the motor is now controlled to draw a constant amperage. In this way a change in sludge viscosity or density caused by a sudden slide of material to the thickener discharge cone is taken care of by a change in pump rpm.

To achieve 25-30% sludge density, 95-98% of the sludge must be recycled. At Waite-Amulet, two Worthington 3" x 3" horizontal rubber-lined slurry pumps were installed as slurry recycle and sludge waste pumps. One heavy duty AC motor and a single controller were selected for the variable speed sludge recycle pump.

The sludge recycle pump and sludge waste pump are located in a pit under the thickener which minimized the length of the suction line to the pumps. One Galligher sump pump acts as a backup for either the recycle or waste sludge pump. The sump is designed to discharge its overflow to the clear water overflow ditch.

Recycle flow monitoring is by a Taylor mag-pipe flowmeter installed on the sludge recycle line. The purpose of the sludge flow measurement is to be able to optimise the flocculant/recycle ratios and to shut the plant down automatically if the recycle sludge volume drops below a preset limit.

Sludge Disposal

Once sludge density has been reached, the sludge waste pump is activated for a timed period by an ultrasonic sludge level detector supplied by:

NATIONAL SONICS DIVISION
Sensall Control
Xertex Corporation
Hauppauge, NY 11787

To minimize the amount of spare parts, this pump is identical to the recycle pump but with a standard AC motor which is feasible because the sludge pond is only 300-400 feet from the treatment plant and at the same elevation.

The sludge disposal line is insulated and has a 1½% slope back to the treatment plant. After every sludge purge the line will be flushed. The waste pump header is connected to the upper part of the clarifier and, by means of automated knife valves, some of the clear water will be used for the flushing of the line by the waste pump. After the flushing sequence has been completed an automated knife dump valve will be activated to drain the line.

Sludge production is estimated at 2.6 acre-ft/year, and a 10 acre-ft sludge disposal pond has been constructed adjacent to the plant.

The sludge impoundment system is fitted with a porous base of sand and pebble size slag drains to drain the sludge to 50% solids. The impoundment is divided into three sections which are cycled to provide maximum drying before being covered with fresh material.

During winter, dewatering is limited but as the spring thaw arrives, the drainage characteristics of the once frozen material is greatly enhanced. In summer, drying will remove additional moisture causing shrinking and cracking which allows air to come into contact with the sludge. There will be some conversion from ferric hydroxide to the carbonate as well. This results in a very stable dry sludge.

Leach tests of a similar sludge by COMINCO at Kimberly, B.C., are said to have resulted in virtually no dissolution of heavy metals but more information on this could be requested from:

MR. WALTER KUIT
Cominco Ltd.
200 Granville Street
Vancouver, B.C.
V6C-2R2
(604) 682-0611

At Waite-Amulet, the storage ponds are about 300 feet x 500 feet long divided into three sections with clay dikes and a usable storage height of 5 feet.

Dry sludge production rate is estimated at 4,000 tpa or 2.6 acre-ft/year. A truck hauling program will be instituted when needed to move dry sludge to one of the tailings sites for final deposition.

The drainage pipes from the sludge depositions exit to a drain for gravity flow to the acid feed water reservoir. In the future, this water could be diverted to the clear overflow ditch once its good quality has been confirmed.

Control System

A very innovative automatic control system has been installed at the Waite-Amulet water treatment plant. The heart of the system is a programable Texas Instruments micro-processor which is equipped to handle on/off analogue input/output as well as timing, counting and arithmetic functions. The input/output configurations are simple and easily traceable in the event of malfunction or logic error.

The micro-processor has three prime functions:

1. Generating temporary shutdown on critical alarm.
2. Monitoring and recording of plant operation.
3. Restarting the plant after power failure.

The plant is also equipped for manual operation by manual on-off switches on the central control panel although it is intended to operate the plant as a remote, unmanned automatic unit.

Proposed Water Treatment Plant at Waite Amulet

Site Arrangement

Actual Installation is slightly different

Proposed Waite Amulet Water Treatment Plant Building
General Arrangement - Elevation View

Actual Installation is slightly different

Proposed Water Treatment Plant at Waite Amulet

General Arrangement - Top Floor

Actual Installation is slightly different

The microprocessor is programmed to handle a variety of contact switches associated with field instruments:

- High pH at neutralization tank #1.
- Polymer delivery line pressure.
- High sludge bed level.
- High efficient turbidity.
- High clarifier rake torque 70% of maximum rated torque.
- Medium high clarifier rake torque at 40% of maximum rated torque.
- Low pH in neutralization tank #1.
- Low water supply pressure.
- Low compressed air pressure.
- Low raw water pond level.
- Low sludge recycle flow.

Services

The water treatment plant facility totals 150 HP installed power and 75 KW for heating during the coldest days. Cost of installing the 25KV line for the installation was $55,000.

The microprocessor is connected by telephone line to the Horne Division to continuously transmit plant operating status and for communications with the plant operator.

The plant also needs 60 igpm fresh water to operate. This is supplied by installation of one two-stage Flygt pump in a heated well alongside the Duprat River about 1500 feet from the plant to provide fresh water for polymer preparation, lime slurry preparation and transport, pump glands, and for floor washing.

Acid mine water treatment at Les Mines Gallen, Noranda Mines Limited

N. LECUYER
Chief Engineer, Chadbourne Division
Noranda Mines Limited
Noranda, Quebec

ABSTRACT

During early 1980, pre-production work commenced at the "Les Mines Gallen" project, north of Noranda, Québec. As a result of the acid mine water associated with this property, a major pre-production phase included the installation of a water treatment plant to render the water environmentally suitable.

This paper emphasizes the planning, installation and operational factors of the treatment plant necessary to the success of the mining operations and the maintaining of a clean environment.

Introduction

The Gallen Project is a zinc, gold and silver open-pit mining operation approximately 10 kilometres north of Noranda, Québec. This property has a long history, with initial diamond drilling done in the early 1930s and underground mining taking place between 1953 and 1962. This property was reactivated in 1980, with production scheduled at a rate of 45,000 tons per month.

Included in the reactivation plans for the property was the installation of a water treatment plant to treat the acidic mine water.

Plant Design

The requirements for the Gallen water treatment plant were two-fold. Firstly, it was necessary to neutralize the acid water and secondly to produce a sludge containing metal hydroxides and sulphates which would be stable when stored, and a clarified overflow meeting governmental regulations to be discharged to the environment.

The flow sheet (Fig. 1) will explain the process in treatment of the acid water.

Acid mine drainage is treated with lime to increase the pH to 9.50. Metals in solution are precipitated as metal hydroxides and the SO_4 as calcium sulphate. The precipitate slurry is then aerated to convert ferrous iron to ferric iron, which is more stable for storage and disposal.

The precipitate is next flocculated with a polymer flocculant and settled in the thickener to produce a sulphate/hydroxide sludge and a final effluent discharged to the environment.

The initial plant design was based on a flow rate of 400 l.g.p.m. From this, the plant specifics, such as reactor capacities, flow rates, thickener capacity, etc., were designed. The consultant for the design stage was P. Shibley and Associates, with Mining Corporation of Canada responsible for all engineering drawings, including all fabrication and erection details.

Construction on the plant building was started in August 1980, with plant start-up initiated in early April 1981.

Norman Lecuyer

Norman Lecuyer is a native of Noranda, Québec. He is a graduate of the Northern College, Haileybury School of Mines, and a graduate of Queen's University in mining engineering. His work experience includes various positions with Pamour Porcupine Mines Ltd. and Mining Corporation of Canada Limited. He is currently chief engineer with Noranda Mines Ltd., Chadbourne Division.

Keywords: Underground mining, Les Mines Gallen, Water treatment, Noranda Mines, Environmental control, Acid mine water.

FIGURE 1. Location of Les Mines Gallen.

FIGURE 2. Block diagram of the Mines Gallen flow sheet.

Theory of Operation

The plant operation can best be explained by the use of a schematic flow sheet (Fig. 2).

Prior to plant start-up, it is necessary to perform bench tests to determine neutralization and flocculation requirements in order to start nearest to the optimum lime and flocculant flow rates.

The acid mine water flows into neutralization reactor 1 from the mine, where lime is added on initial start-up. Once all tanks are filled, the lime is introduced to the sludge recycle tank. Neutralization takes place in the two reactors, the second of which is utilized to provide for retention time for the reactions to complete. These reactions may be summarized as follows:

$$Ca(OH)_2 + \text{Metals} - \begin{array}{ll} CaSo_4 \text{ ppt (insoluble)} & \\ Cu(OH)_2 \quad \text{ppt} & \\ Zn(OH)_2 \quad \text{ppt} & \\ Fe(OH)_2 \quad \text{ppt} & \\ Mn(OH)_2 \quad \text{ppt} & \end{array} \left.\right\} \text{insoluble ppt}$$

The hydrated lime slurry increases the pH from an average of 3.50 to 9.5. Achieving a pH of 9.5 is very important, because this provides for the best formation of sludge in the thickener. The lime is stored in a 100-ton lime bin and fed via a vibrating screw feeder into a cone where water is added to produce a slurry, which is then pumped to the recycle tank.

The lime flow is automatic. The pH meter, located in neutralization reactor 2, feeds a signal through an interface controller which increases or decreases the lime feed rate depending on the pH in the tank.

From reactor 2, the overflow goes into the thickener via a flash mixer, where the flocculant is added to promote flocculation and rapid settling of the sludge. The flocculant is prepared in the B.I.F. (basic inflow) system and pumped to the flash mixer. To date, the flocculant used is the dry polymer, Percol 156. The flocculant is prepared as a 0.1% solution or as required, depending on the flow rate of the incoming water.

The sludge precipitates in the thickener to approximately 35 per cent of the original inflow, but will be of a very low density. To provide for a high-density sludge, the High-Density Sludge System was incorporated whereby recycled sludge from the thickener underflow is premixed with lime for neutralization before adding it to the incoming mine water. This provides a change in the physical chemistry of the sludge which promotes the growth of larger and consequently faster-settling high-density sludge. Sludge densities of over 20 per cent have been obtained to date.

The thickener is equipped with two Lamella plate packs which provide high surface area for clarification. The thickener underflow is split between the sludge discharge and sludge recycle. The sludge recycle volume can be up to 50% of the mine water flow.

The sludge discharge is automatic. A sludge level control system is utilized, which consists of an ultrasonic sensor which activates the sludge discharge pump when the sludge attains the desired level in the thickener. This sludge is discharged to the sludge basin for storage and will eventually be covered and revegetated.

The thickener overflow or effluent is discharged to a polishing pond, from where it discharges into the Kinojevis river system.

Plant and Associated Construction

Construction for the treatment plant consisted of the plant itself as well as the sludge basin (necessary for storage of the sludge), polishing pond, diversion ditch and a fresh-water line from Lake Dufault.

The sludge basin area selected was an area where a natural depression existed that would facilitate construction. The sludge basin and polishing pond area required some 90,000 cubic yards of excavation. The overflow of the polishing pond goes into the diversion ditch, a ditch 1,500 feet long to drain the water into the Kinojevis river system.

The process water line from Lake Dufault is a 3-inch-diameter line, approximately 2,500 feet long, which supplies the plant process water for the polymer mix system and the lime feed system.

The plant is housed in a 45-foot-wide, 100-foot-long, 35-foot-high building. The building also houses the two-bay garage, and both plant and garage can be serviced by a 3-ton overhead crane.

Lime storage is provided for by a 56-foot-high by 15-foot-diameter Butler bolt-a-tank, which is equipped with a vibrating screw feeder and bin activator.

The thickener tank is a 26-foot-diameter by 20-foot-high tank constructed of quarter-inch steel and having a working capacity of approximately 63,000 Imperial gallons. The reactor tanks are 12-foot-diameter by 16-foot-high tanks having a working capacity of approximately 9,000 gallons each.

Flocculant preparation is done using the B.I.F. (basic inflow) system. Dry polymer is fed automatically into a mixer, mixed with water and flows into the mixing tank (200 gallon cap.). After mixing, the solution is transferred to the holding tank (400 I. gallon cap.), from where the solution flow to the thickener is effected by a metering pump set to deliver the required concentration of flocculant solution.

The nerve centre of the plant is the control room. The control room houses the motor control centre, control console and the instrumentation panel. The operators control console permits the operator to see at a glance that all plant systems are functioning. The instrumentation panel continuously records the mine water inflow, the pH in reactor two and the effluent discharge and the turbidity of the discharge. The instrumentation also provides for automatic plant shutdown. A plant shutdown is effected when a critical point in the system fails. These critical points include:

(1) drainage inflow variation below set-point;
(2) significant fluctuation of the pH;
(3) turbidity of effluent above the set limit;

FIGURE 3. Schematic diagram of the Mines Gallen flow sheet.

(4) fresh water supply failure to flocculant or lime system;
(5) air supply for aeration failure below set limit;
(6) high sump level; and
(7) high level on effluent discharge.

Capital costs for the plant are approximately one million dollars, which includes the building, foundation, plant electrics, tanks, pipelines, plant equipment, engineering, etc.

Plant Operation

The Gallen treatment plant started operations on the 4th of April, 1981.

Initially, the drainage inflow was limited to approximately 25 per cent of plant capacity due to an undersized pump. Initial problems included discoloration or suspension of the precipitate in the thickener tanks as a result of ineffective flocculation. The problem was resolved by adjustment of two items. Firstly, it was apparent that initial flocculant preparation or mixing was not sufficient, whereby the polymer was coagulating due to insufficient mixing. Secondly, the point of injection of the flocculant was moved 5 to 6 feet upstream of the flash mixer to provide more contact time with the precipitate. It was also found that the flash mixer tended to break up the effect of the flocculant and this was removed from the system. With the above-mentioned adjustments, the flocculation and settling took place rapidly, with a clearing up of the thickener solution and excellent effluent quality.

Combined with the above, it was necessary to balance the flocculant dosage, which required a period of time, with the present consumption at 6 p.p.m.

Adjustments and changes to the lime system were also required. The initial 1-inch lime slurry line proved to be undersized, and installation of a 2-inch line to reduce losses eliminated plugging. Problems were also experienced with the screw feeder, which tended to plug on occasion due to its intermittent operation, based on lime demand from the pH loop in reactor two. This was solved by assuring that the screw feeder rotates at a slow speed when lime demand is low rather than stopping completely. Lime consumption to date is averaging 18.5 pounds per 1000 gallons.

FIGURE 4. Plant shutdown control.

The sludge recycle rate is now 145 I.g.p.m., or about 50 per cent of the drainage inflow to the plant. At this rate, the flocculation and settling rates are very good. The per cent solids on the sludge discharge and recycle has built up to a point where the averages for the months of June and July 1981 were 9.5% and 23.53% respectively.

Although there were some problems with effluent quality during the first month or so because of balancing of the plant, the effluent quality is now within the governmental regulations, as indicated by the following comparison:

Gov. Requirements (p.p.m.)		Plant Effluent (p.p.m.)
Cd	0.05	0.021
Cu	0.15	0.039
Fe	3.00	0.750
Pb	0.20	0.160
Zn	0.50	0.45
pH	5.5 to 9.5	6.5 to 9.0

It is apparent that the plant is doing its job. There is also room for improvement here on the optimum flow rates, concentrations and recycle rates. This of course, comes with operating experience and requires some time.

An estimate of plant operating costs is as follows. It must be pointed out that this is based on the first four months of operation, during which time flow rates were not at maximum and balancing of the plant was required.

Item	Cost/1000 I. Gallons
Hydrated Lime	.848
Flocculant (Percol 156)	.107
Power	.658
Labour	.300
TOTAL	$1.913

The above figures are those for a single operator. Eventually, it is planned to operate the plant without a full-time operator, whereby plant tests for sludge quality, etc., can be performed on a routine basis which should require only several hours per week. Thus, costs at that time would be in the order of .1 to .2¢ per Imperial gallon treated.

Conclusions

Although it required some time to balance the treatment plant at Gallen, present results are very good. Most problems have been mechanical ones to date—pumps, motors, electrical defects, etc.

Most important is the fact that the sludge densities sought have been obtained with an effluent discharge that meets governmental requirements. Work is also continuing to optimize and reduce costs where possible.

Our main object is to carry out the mining operations at Gallen while maintaining or improving the environmental conditions, which in this day and age have become a prerequisite for the mining industry.

5. Cu-Pb-Zn Mine-Mill M, Ontario

Note: This data has not been verified and may be unreliable.

This early HDS water treatment plant is of particular interest here because acid mine drainage, consisting mainly of tailings reclaim water is high in zinc relative to iron. In other words, this HDS plant removes a sludge with a high zinc/iron ratio which is atypical of the other plants discussed to date.

HERMAN (1983) showed that zinc can be effectively removed in an HDS operation even in the absence of iron.

Composition of tailings pond decant solution, i.e., feed to the treatment plant, varies in summer and winter as follows.

	Winter		Summer		
	Treatment Plant		Treatment Plant		Retention
	Influent	Effluent	Influent	Effluent	Pond Effluent
pH	10.0	10.2	7.0	10.5	9.3
Fe	0.10	0.48	0.88	0.04	0.88
pB			LT 0.06	LT 0.02	0.02
Zn	0.80	0.76	3.14	0.20	0.1-0.3
Cu			LT 0.01	LT 0.01	LT 0.01
S_2O_3			Tr	4.1	Tr
S/S	7.0	Tr	1.0	Tr	1.0
Temp.			16.5°C	17°C	14°C

LT = Less Than

The HDS water treatment plant treats 600 Igpm (3900 m^3/d). It is noted that the quality of the reclaim tailings pond water varies from summer to winter. In summer dissolved Zn levels increase to over 3 ppm, and the pH of the tailings return water is lowered.

Recycle sludge from the Lamella thickeners is mixed with lime in a ratio 90:10 using air to mix the sludge. The process is operated at pH 9.5 and also uses Lamella thickeners. However, this time Pilkenrood Lamella plate thickeners were used.

Following two stages of neutralization, flocculant is added in two points into a long series of S-bends carrying the solutions ahead of the Lamella thickener.

Percol 155 flocculant is added at a dose of around 1 ppm.

The sludge from the thickener-clarifier runs 15-20% Zn, and operators say that sludge density must be kept up in order to keep the clarifier working correctly. The precipitation process, being mainly zinc-oriented, is operated at pH 9.5. It is found that if the pH gets above 10, then the flocs are light and tend to get lost in the clarifier overflow.

In this case, the precipitated sludge at 15-20% zinc represents an economic value, and the sludge has at times been disposed of by adding it to the zinc concentrate for shipment to a refinery.

CONVENTIONAL NEUTRALIZATION

Conventional neutralization of AMD can be achieved by reaction with several reagents including lime, limestone, sodium hydroxide, soda ash, and ammonia. Ammonia may be the most effective and least costly in several locations, but it is unsuitable for AMD treatment for dischargeable effluents because of the undesirable environmental effects on fish to which ammonia at high pH is toxic down to 10 ppb. One of the main disadvantages of lime precipitation is the voluminous sludge that requires very large impoundments and which takes many, many years to stabilize for site reclamation.

Unstable Voluminous Sludge from Conventional Lime Precipitate of AMD

An example of the different results that can be achieved when using some of the various neutralizing reagents to treat AMD from a South African coal mine is illustrated in the following graph from BOSMAN (1974):

Fig. 1—Settling rate of precipitate from Kromdraai neutralized water
A—Lime 0,875 g/l Solids in sludge 0,8%
B—Limestone 0,83 g/l + lime 0,47 g/l Solids in sludge 1,7%
C—Limestone 1,10 g/l Solids in sludge 2,7%

—Neutralization of Kromdraai acid drainage with different types of lime and limestone

A comparison of various treatment processes including the cost of various neutralizing agents was published by HOLM & SIMPSON (1981) for a Colorado mountain location and reported as follows:

Estimated Range of Costs for Treatment

Method	Estimated Cost Range, dollars/1000 gal.
Lime neutralization	0.20 to 1.30
Limestone neutralization	0.15 to 1.00
Soda ash neutralization	0.40 to 3.00
Sodium hydroxide neutralization	0.50 to 3.50
Reverse osmosis treatment	1.00 to 5.00
Ion exchange treatment	1.00 to 7.00

Although probably not based on a rigorous engineering study, the ranges of costs in the above table do illustrate the relative costs quite well. Additional discussion of the relative merits and performance to be expected by lime and limestone precipitation is included in the following excerpt from a 1975 review on the subject prepared by Environment Canada. One item in particular that was found to be interesting was the fact that even ferric hydroxide forms higher oxide complexes, and that ferric hydroxide is also amphoteric, as well as zinc, copper, and aluminum.

OXIDATION OF FERROUS TO FERRIC IRON

BOSMAN pointed out the wellknown fact that if conventional air agitation is used, then the rate of ferrous to ferric oxidation is highly pH dependent, being much higher at pH 8 and 9 or above than in the acid pH range.

Also, if iron can be converted into the ferric state, it can be removed from solution by precipitation as ferric hydroxide at relatively low pH values, thereby requiring less lime or NaOH addition.

MIHOK (1969) reported the interesting phenomenon that ferrous iron can be efficiently oxidized to ferric iron even at low pH values around pH 2.5 using a short contact time with activated carbon and air.

Ferrous iron content of an acid minewater flowing through an aspirated activated carbon column was reduced from about 700 ppm to about 10 ppm in less than a minute.

MIHOK (1969) reported that activated carbon was used repeatedly with little loss in efficiency, no discoloration, and no solids deposition. In the batch tests, about a third of the iron was adsorbed by the carbon but with continuous flow, little iron adsorption was expected.

By

Environment Canada WPCD Staff
Report EPS 3-WP-75-5 Dec. 1975

4. WASTEWATER TREATMENT PROCESSES

The specific wastewater problems and treatment requirements of a particular mine are subject to the influence of local circumstances. These include the mineralogy of the ore body and surrounding area, climate and topography. However, the overall problem faced will be composed of an aggregate of discrete units determined by the contaminating factors described in Section 3.

In this section, descriptions are provided of the basic wastewater treatment processes. Emphasis is placed on demonstrated, practicable solutions applicable to Canada.

4.1 Acid Neutralization and Heavy Metal Removal

Acid is generated through the oxidation of iron sulphide minerals. This acid is then available for leaching metals from the minerals.

The characteristics of a range of typical acid waters is given in Table 2. In their untreated form, these wastes are extremely toxic to fish and other forms of aquatic life and do not comply with many basic requirements for potable water. Any process used to neutralize acids will also remove dissolved heavy metals through the formation of insoluble metal hydroxides. The conditions necessary for hydroxide formation are considered below.

4.1.1 Hydroxide formation

Heavy metal precipitation occurs as a result of the reaction $M^{++} + 2OH^- \rightarrow M(OH)_2$, where M is the metal cation. Many metal hydroxides are in fact precipitated as the hydrated metal complex $M(OH)_2 \cdot nH_2O$, even from simple solutions of the metal.

The precipitation of heavy metal hydroxides can be predicted by using standard solubility relationships where the solubility product, Ksp, for the above general reaction is given by:

$$KsP = (M^{++})\ (OH^-)^2$$

Since the OH^- ion concentration is a function of hydrogen ion concentration, the degree of precipitation of a given metal hydroxide is directly related to pH:

$$(OH^-) = 10^{(pH-14)}$$

TABLE 2. TYPICAL ASSAYS OF ACID WATERS IN CANADA

(All Concentrations are mg/l except pH)

Type of Operation	Cu - Pb - Zn (Mine & Surface Drainage)	Cu- Pb -Zn (Mine Water)	Uranium (Seepage)	Cu - Zn (Active Mine)	Base Metal (Abandoned)	Uranium (Abandoned Mine)
pH	4.0	2.0	2.0	3.0	2.6	2.0 - 2.8
Suspended Solids	8.8	690	Nil	-	-	25
Total less solids	79	24,000	-	-	9,200	13,440
Hardness	293	2,960	-	-	1,390	
Ca	-	-	416	-	454	-
Mg	-	-	106	-	178	-
Cu	17	11	3.6	0.0	2.5	2.2
Zn	118	1,090	11.4	0.4	34	9.4
Pb	0.4	58	0.7	0.11	0.5	-
Fe (total)	79	1,830	3,200	11.7	1,300	300
Mn	21	0	5.6	0.4	8.2	3.6
SO_4	36	16,560	7,440	885	4,050	6,900
COD	-	245	270	-	110	-

Thus, for simple precipitation, if the solubility product constant is known, a plot of metal ion concentration against pH can be drawn from which the optimum level of precipitation and corresponding pH can be determined.

The calculations are more complex if the precipitated compound is amphoteric or if the composition of the waste is such that several compounds precipitate simultaneously.

Amphoteric precipitates, such as many heavy metal hydroxides, exhibit minimum solubility at a distinct pH level and an increase in solubility as pH is shifted in either direction. The pH level of minimum solubility can be evaluated from solubility product and chemical equilibrium relationships of the appropriate ampholytes. Such an exercise has been attempted for copper, zinc, lead and iron and the resulting plots are presented in Figures 1 to 4.

Several factors preclude the possibility of theoretically deriving absolute values for best residual levels of metal ions. Not the least of these is the extremely broad range of solubility products for most of the metallic salts in question.

Bearing in mind the above-mentioned limitations, the following ranges of residual metal concentrations and optimum pH values appear to be theoretically feasible if total precipitate removal from the decant can be achieved.

Cu	1 - 8 µg/l	pH 9.5
Zn	10 - 60 µg/l	pH 10
Pb	< 1 µg/l	pH 8
Fe (total	< 1 µg/l	pH 8 (if totally oxidized to ferric)

It is evident that, at best, theoretical solubility product relationships can give only a broad indication of the metal concentrations attainable by treatment methods using precipitation.

Figures 1 to 4 indicate that the following pH sequence should theoretically result in an optimum removal of metals from solution:

pH 8 - maximum removal of iron as $Fe(OH)_3$ and lead as $Pb(OH)_2$

REACTIONS:

$Fe(OH)^{+2} = Fe^{+3} + OH^-$	$K = 1.5 \times 10^{-12}$
$Fe(OH)_2^+ = Fe^{+3} + 2\ OH^-$	$K = 5.6 \times 10^{-22}$
$Fe(OH)_3\downarrow = Fe^{+3} + 3\ OH^-$	$Ksp = 10^{-38}$
$Fe(OH)_4^- = Fe^{+3} + 4\ OH^-$	$K = 10^{-33}$
$Fe(OH)_2^{4+} = 2\ Fe^{+3} + 2\ OH^-$	$K = 7 \times 10^{-26}$
$Fe(OH)_2\downarrow = Fe^{+2} + 2\ OH^-$	$Ksp = 3.2 \times 10^{-14}$

Figure 1. Iron Solubility (3)

REACTIONS:

$Cu(OH)^{+} = Cu^{++} + OH^{-}$	$K = 10^{-6}$
$Cu(OH)_2 = Cu^{++} + 2\ OH^{-}$	$Ksp = 2 \times 10^{-19}$
$Cu(OH)_3^{-} = Cu^{++} + 3\ OH^{-}$	$K = 6.2 \times 10^{-16}$
$Cu(OH)_2^{-} = Cu^{++} + 4\ OH^{-}$	$K = 7.7 \times 10^{-17}$
$Cu(OH)_2^{++} = 2\ Cu^{++} + 2\ OH^{-}$	$K = 10^{-17}$

Figure 2. Copper Solubility(3)

REACTIONS:

$Zn(OH)^+ = Zn^{++} + OH^-$	$K = 9.1 \times 10^{-6}$
$Zn(OH)_2\downarrow = Zn^{++} + 2\ OH^-$	$Ksp = 4.5 \times 10^{-17}$
$Zn(OH)_3^- = Zn^{++} + 3\ OH^-$	$K = 1.75 \times 10^{-14}$
$Zn(OH)_2^- = Zn^{++} + 4\ OH^-$	$K = 8 \times 10^{-16}$

Figure 3. Zinc Solubility (3)

REACTIONS:

$Pb(OH)^{+} = Pb^{++} + OH^{-}$ $\quad K = 1 \times 10^{-6}$

$Pb(OH)_2 \downarrow = Pb^{++} + 2\ OH^{-}$ $\quad Ksp = 1.1 \times 10^{-20}$

$Pb_4(OH)_4^{4+} = 4\ Pb^{++} + 4\ OH^{-}$ $\quad K = 1.8 \times 10^{-37}$

Figure 4. Lead Solubility (3)

pH 9 - 9.5 - maximum removal of copper as $Cu(OH)_2$

pH 10 - maximum removal of zinc as $Zn(OH)_2$

In practice, it is unlikely that such a sequence would be either feasible or worthwhile. In cases where the theoretical relationships apply, it is probable that better overall results and reliability would be achieved by closely controlling the pH at 9.5 to 10. In this way good copper and zinc precipitation should be achieved with only slightly less efficient removals of iron and lead.

Ferric iron precipitation commences at pH 3 and is complete by about pH 8. Harrison (4) reports that total ferrous removal is achieved at pH 9.5 but other sources (3) suggest that higher pH values may be required as indicated by the superimposed Fe^{++} solubility line on Figure 1.

Other factors precluding the derivation of absolute values include:

- The effect of mixed metal hydroxide complexes of the general form $(M_1)_a(M_2)_b(OH)_c \cdot nH_2O$ is difficult to predict. Solubility product calculations can be applied accurately only if the ratio of concentrations of the precipitating substances is stable. This is unlikely in most practical applications.
- Data on ampholytes are limited but, where available, such data have been used in the derivation of Figures 1 to 4. The assumption that all indicated ampholytic species of a metal will exist in a solution is conservative. For example, in the case of copper it has been assumed that $Cu(OH)_2$ precipitates, and $Cu(OH)^+$, $Cu(OH)_3^-$, and $Cu(OH)_4^=$ remain in solution.
- Chelation of metal ions by organic compounds in the tailings pond can further influence actual ion concentrations.

4.1.2 Neutralizing reagents

Reagents which have been used for neutralization of acid mine water include:

- limestone,
- lime,
- sodium carbonate, and
- sodium hydroxide.

In the iron ore industry, where flotation is practiced, the circuit is quite often run at a pH of 9 - 11.5. For effective flocculation of slimes in tailings the pH should be neutral. The neutralizing agent most commonly used is sulphuric acid.

The relative costs and advantages of these reagents are summarized in Table 3. This information was developed on materials costs and supplies at a particular location in New Brunswick. Transportation costs, reagent purity, and the availability of materials may provide a different cost analysis in other parts of the country. It is evident that on a cost basis alone, limestone and lime are the most attractive, with limestone being the cheaper when compared in terms of relative basicities. The effect of dolomite content has not been considered but can be a major factor. Several serious disadvantages are associated with the use of limestone, particularly its inability to produce pH's higher than about 7 and its tendency to produce a surficial layer of gypsum ($CaSO_4$) and gelatinous metal hydroxides, which reduces its reactivity unless mechanically removed by sparging or tumbling. Lime is, therefore, the most common reagent used for pH adjustment in base metal mine effluent treatment and results in the metal being precipitated as the hydroxide.

In certain instances it is advantageous to consider the use of mixtures of limestone and lime. In such cases limestone is applied initially with final pH adjustment made with lime. The factors which have to be assessed include:

(i) unit reagent costs and daily tonnage requirements;
(ii) availability of supply;
(iii) reaction period necessary for neutralization (limestone can require up to 48 hours contact before the reaction is complete);
(iv) capital and operating costs of dual materials handling system;
(v) sludge handling and stability;
(vi) process control; and,
(vii) freight costs for reagents.

TABLE 3. ALKALI CHARACTERISTICS

Reagent	Formula	Basicity Factor*	Approximate Cost (¢/lb)	Relative Cost/ Unit Basicity (cents)	Relative Advantages and Disadvantages
Limestone	$CaCO_3$	1	0.4	0.4	Suitable for pH < 7 only. Lower reactivity than lime. Potential surface coating problems with gypsum. Handling costs may be relatively high - crushing, high bulk storage, etc. High CO_2 production.
Lime	$Ca(OH)_2$	1.75	1.25	0.71	High reactivity - relatively easy bulk handling, high pH attainable.
Ammonium Hydroxide	NH_4OH	2.85	8	2.80	Nitrogen nutrient enrichment has eutrophication implications in some regions. NH_3 toxic to fish at high pH and low DO.
Sodium Carbonate	Na_2CO_3	0.91	3	3.30	Less basic yet more expensive than limestone or lime. High CO_2 production.
Sodium Hydroxide	NaOH	1.25	5	4.0	Cost prohibitive - very fast reacting, complete pH range effectiveness.

* $CaCO_3$ = 1 (100% utilization of available alkalinity assumed)

Finally, it must be emphasized that the reactivity and thus the cost/effectiveness of different sources of lime and limestone vary tremendously. Generally, dolomitic limestone and high magnesium lime are less reactive than low magnesium sources.

Reactivity should generally be assessed on the basis of available CaO or $CaCO_3$. It is recommended that each application be individually assessed.

It should be noted that metals precipitated by both limestone and sodium carbonate may be in the form of basic metal carbonates; these may be less soluble than the equivalent hydroxides. Sodium carbonate also has the advantage of dispersing slimes that might otherwise float on the surface of the tailings pond and be discharged with the overflow.

The use of ammonia for neutralization is not recommended. Ammonia is an acutely toxic substance even at low concentrations and it is the recommendation of this working group that the use of ammonia for neutralizing acid wastewater be prohibited.

4.1.3 Point of addition

Some basic observations may be made with respect to the point and manner of addition of the neutralizing reagents. Both lime and limestone require a finite reaction time before the neutralizing capacity is fully realized. The required reaction time is very much larger in the case of limestone. This must be taken into account in the original process design, which must establish conditions of intimate contact between the reacting species for as long as is necessary. Clearly this is not achieved if the neutralizing agent is allowed to settle out in a tailings pond or lagoon before it has reacted with the bulk water phase. It may be necessary to provide vessels or use a slurry pipeline or launder as reaction chambers.

4.2 Ferrous/Ferric Oxidation

In order to precipitate ferrous hydroxide a solution pH of 9.5 is required. On the other hand, ferric iron precipitates sufficiently by pH 4.5, although the minimum level as previously indicated is reached at a pH of 8. Thus, there are substantial potential advantages in being

able to oxidize ferrous iron to the ferric form and complete the precipitation at lower pH values. Both chemical and biological oxidation processes have been evaluated. The general equation:

$$4FeSO_4 + 2H_2SO_4 + O_2 \rightarrow 2Fe_2(SO_4)_3 + 2H_2O \qquad (18)$$

describes the reaction.

4.2.1 Chemical oxidation

Ferrous iron may be oxidized by atmospheric oxygen. The reaction is strongly pH dependent and occurs almost instantaneously (less than 1 minute) at pH values greater than 7.2. At a pH of 6.5 the reaction takes in excess of 1000 minutes. See Table 4.

The importance of the pH has a major cost impact on two interrelated factors: the size of the oxidation reactors; and, the neutralizing agent used for pH adjustment. If the cheaper limestone is used, then a substantial equilibration period is required to approach, if practical, pH values in excess of 7. Thus, large reaction chambers would be required for both neutralization and oxidation. Alternatively, lime could be used to provide rapid neutralization to a pH level sufficient for almost instanteous oxidation. The attendant implications with respect to sludge production and handling are discussed in Section 4.5.

In the majority of installations treating solely iron bearing acid waters lime or limestone/lime combinations are employed. Different cost evaluations must be applied to waters containing dissolved zinc, nickel, etc. In these cases pH values in excess of 9 will be required to precipitate the metal hydroxides. Consequently, lime handling facilities will be required independent of what material is used to facilitate the iron oxidation process.

4.2.2 Biological oxidation

Biological oxidation of ferrous iron can be effected by the acidophilic bacterium *Thiobacillus ferrooxidans*. The process consists of controlled bacterial oxidation in a balanced nutrient medium. The process is conducted under acid conditions in the range of pH 1 to 4. The potential advantage of this process is that ferrous iron oxidation is carried out under acid conditions, and thus the converted ferric iron

TABLE 4. DETENTION TIMES (MINUTES) REQUIRED TO OXIDIZE FERROUS IRON (Temperature 10°C)

pH	100 mg Fe/l	500 mg Fe/l	2500 mg Fe/l
5.0	7.8×10^5	1.1×10^6	1.4×10^6
6.0	7.8×10^3	1.1×10^4	1.4×10^4
7.0	7.8×10^1	1.1×10^2	1.4×10^3
8.0	7.8×10^1	1.1×10^0	1.4×10^0

Initial Fe^{++} Conc. mg Fe/l	Temperature °C		
	10	20	35
10	0.001*	0.003	0.003
100	0.009	0.013	0.018
500	0.011	0.035	0.053
1000	0.017	0.040	0.080

* oxidation rate g Fe/l/hr

may be precipitated at pH values readily attainable through limestone neutralization. Completely stirred tank reactors (CSTR) can meet process requirements. However, the bacteria do not possess satisfactory auto or induced flocculation characteristics. This means that clarification and sludge recirculation cannot be practiced, with the result that bacterial populations are limited by those generated in a single pass oxidation process. If bacterial populations could be increased then the kinetics of the process would improve proportionately. This has been achieved through the use of fixed film reactors. In this approach, bacteria are developed on inert surfaces and exposed to the liquid. As the population increases, so does the number of bacteria exposed to a unit volume of iron bearing wastewater. Both packed column and biodisc treatment processes function in this way, with the biodisc exhibiting a higher efficiency than the packed column.

The process is first order dependent on the ferrous iron concentration and oxygen pressure, and directly proportional to the second power of the hydroxide ion concentration.

Oxidation rates are also strongly temperature dependent at any given pH. See Table 5. This results in residual ferrous iron concentrations that are too high and thus still require pH elevation to 9.5 for complete removal. This is especially the case at low temperatures, i.e. less than 5°C. Further process development is underway.

4.3 Co-precipitation and Adsorption

Co-precipitation is a phenomenon associated with the precipitation of one component from a multi-component system. Component 'A' may be converted to an insoluble form and in so doing may remove a fraction of component 'B' from solution. Under equilibrium conditions component 'B' should have remained in solution.

This phenomenon may be employed advantageously in the precipitation of metal hydroxides. Rapid pH adjustment, resulting in maximum instantaneous hydroxide formation, should result in increased co-precipitation effects, i.e. removal of dissolved materials. This would be in comparison with gradual addition of neutralizing agents and sequential equilibration. The precipitate of calcium sulphate from saturated solutions may also be effective in this regard.

The co-precipitation of radium with barium sulphate is considered in Section 4.8.

Chemical and physical adsorption processes can also be used to advantage in heavy metal removal. Both siliceous and calcareous materials in tailings exhibit affinities for dissolved heavy metal ions. Silica has a zero point of charge in the range of 3 to 4 pH units. At higher pH values it is negatively charged and will adsorb heavy metal ions through electrostatic adsorption. This would also apply to oppositely charged particulates, such as hydroxide particles. This property may be exploited by bringing siliceous gangue into contact with acid waters prior to neutralization. There would probably be a supplementary benefit through improved hydroxide settlement characteristics and sludge consolidation.

Calcareous gangue would act in a manner similar to siliceous materials. It would also effect pH neutralization and hydroxide precipitation. With both classes of materials there would be a finite adsorption capacity which, in practical terms, could not be regenerated. The long term stability of the absorbed contaminants must also be considered. The data available at this time are limited but since the processes are based on ion exchanges it is reasonable to suppose that the absorption is reversible under certain conditions. If large volumes of material are likely to be used in this manner, then stability tests should be run under a variety of field conditions. It should also be recognized that some ions are more easily adsorbed than others. Figure 5 lists data for adsorption on clay of small amounts of metal ions in the presence of large amounts of calcium and sulphate.

4.4 Flocculation/Clarification

In the heavy metals removal process, precipitated hydroxides must be separated efficiently. Gravity sedimentation is universally employed, generally in stilling basins provided by tailings impoundments or lagoons and more rarely in mechanical clarifiers/thickeners. The design and operation of these units is considered in Section 5.

In the majority of cases the hydroxide precipitates are highly flocculated, possess excellent settling characteristics and provide low residual particulates in the supernatant under quiescent conditions.

Figure 5. Metal Ion Adsorption on Clay(5)

The basic factors affecting the settling characteristics are the density of the particulates and the occupied volume. A high proportion of sludge will result in a rapid transfer from free settling to hindered settling, or even zone compaction.

Although by far the great majority of the metals settle rapidly in the flocculated mass, improvements in supernatant quality have been recorded for settling periods of up to three days in the laboratory. This has been attributed to initial supersaturation and gradual equilibration of the hydroxides, with consequent precipitation and sedimentation.

In certain instances the occurrence of pin point, near colloidal flocs with poor settling and supernatant characteristics has been reported. This is especially predominant when low total metal concentrations, in the order of 25 mg/l, are precipitated. Also, exposing well flocculated materials to high shear rates e.g. centrifugal pumps, can result in floc degradation with similar results on settling and supernatant clarity.

When these conditions exist, the flocculant characteristics of the precipitates can be improved through the following:

(i) Recirculation of the settled solids will increase interparticle collision frequencies and thus increase the rate and extent of flocculation.

(ii) Collision frequencies may be increased by gentle mixing; conventional design considerations used in potable water treatment would be applicable.

(iii) Organic flocculants would be effective in improving the efficiency of adhesion of interparticle collisions. It is hypothesized that cationic substituted derivatives of polyacrylamide would be most efficient, although polyethyleneimine could possess the additional advantage of scavenging trace metals from solution through chelation. Moderately hydrolysed charboxy' substituted polyactylamides would be applicable if sludge conditioning was the dominant concern.

4.5 Sludge Characteristics

The metal hydroxide sludges produced in a wastewater treatment process represent a highly concentrated stream of contaminated material.

It is imperative that they be efficiently separated from the purified water and disposed of in such a fashion that they will never re-enter the environment. As the majority of mining operations providing treatment to acid waters use the tailings impoundment as a settlement zone and sludge collection device, this is not recognized as a major problem by the industry. However, the problem can assume striking proportions to those employing separate lagoons for treatment. Also, the advent of mechanical equipment treatment systems will further accentuate the problem. To set the problem in focus, the waste sludge flow from a system treating a concentrated acid water may constitute up to 30% by volume of the raw feed water. At one mine this is equivalent to 9 cu ft of sludge per ton of mill capacity or 50% of the tailings volume.

4.5.1 Basic properties

The basic characteristic of metal hydroxide sludges is their loose fluffy appearance. On standing they consolidate into a gelatinous thixotropic mass that rarely exceeds 2 to 3% solids by weight. The very low density is caused by chemically bound water which resists conventional physical means of dewatering. It is suggested that the water is attached mainly through hydrogen bonding. If the solids concentration of the waste sludge could be increased, then the physical problems of sludge handling and storage would be reduced. Only a freeze/thaw technique appears to hold potential for the dewatering of the low density sludges. In the freezing step the bound water is "stripped" from the hydroxide to form ice crystals. When thawed the water melts and does not rehydrate the precipitates. The resultant sludge consists of comparatively coarse particulates which settle readily to 30% by weight solids. Such a process would be most applicable in those areas that could rely on natural freezing. It is noted, however, that in one location, faced with the disposal of aluminum hydroxide sludges with similar characteristics, a mechanical freezing plant was justified for full scale application.

A different approach is employed in the "high density sludge" process developed by the Bethlehem Steel Corporation. In this method , sludge is returned from a final clarifier and blended with lime before being processed through a chemical ferrous oxidation reactor with the

raw acid water. The waste sludge may be thickened to up to 50% solids by weight. The densification process is dependent on Fe^{++}/Fe^{+++} ratios and its effectiveness in the presence of other heavy metals has not been established. Although the densification process has been attributed to an ion exchange mechanism, this is in dispute.

Certain extremely acid waters have been reported with sulphate concentrations in the order of 20,000 mg/l. In the presence of calcium ions, introduced through lime or limestone, massive calcium sulphate precipitation will occur. This will dramatically improve the sludge concentration. Sludge densities in excess of 35% solids by weight have been achieved.

Similar benefits are reported when a limestone produced sludge is compared with a straight lime sludge. The combined influence of compaction through unreacted limestone particulates, adsorption on the surface of these particles and the probable formation of dense basic carbonates assist in producing a more consolidated sludge. Heat treatment of precipitated ferrous hydroxide to 80°C has the effect of converting it to the dense magnetite form. This process has not been conducted on a demonstration scale.

4.5.2 Sludge stability

The stability of the sludge with respect to the release of metals is generally indicated by the solubility relationships presented in Figures 1 to 4.

If sludge is stored in surface lagoons it will come into contact with precipitation. Rainwater consists of a weak solution of carbonic acid with typical pH values ranging from 5 to 6 units. In industrialized areas pH values as low as 3.2 to 3.5 have been measured in rainwater and snow and are attributed to the presence of sulphur dioxide. Under equilibrium conditions rainwater will redissolve many heavy metal hydroxide sludges, especially zinc, nickel, ferrous and, to a lesser extent, copper hydroxides. Only ferric iron precipitates may generally be considered to be stable when exposed to the atmosphere. The rate of equilibration is slow and may mask the immediate impact of the process under practical conditions. Nonetheless the data indicate that either (a) the sludge must be converted into a completely stable form; or, (b) affected precipitation must be collected and treated; or, (c) sludge must be disposed of so that

it does not come into contact with atmospheric precipitation; or, (d) the metals contained in the sludges must be recovered.

Table 6 lists data illustrating the problem. A sludge was formed using lime neutralization of water from a Cu-Pb-Zn operation. The treated water was of high quality. The sludge formed was then leached for several days at the pH values shown. Even at pH 5 significant amounts of Cu and Zn are leached.

TABLE 6. DISSOLUTION OF Cu-Pb-Zn SLUDGE (14)
(mg/l)

pH of Leach Solution	4.0	5.0	7.0
Cu	1520	47	0.3
Zn	2330	570	5.3
Fe	4.7	0.2	0.5
Wt. Loss (%)	4.0	1.6	1.2

Various sludge conversions to stable forms have been proposed. They include the formation of stable carbonates and silicates, as well as the use of organic gels. The feasibility of applying these techniques to sludges containing zinc, nickel etc. has not been demonstrated. The treatment of contaminated sludge runoff implies a never ending treatment process. Underground disposal of sludge has not been demonstrated in Canada, although the disposal of ferruginous sludges in abandoned mines has been employed in the United States. Zinc and iron have been recovered from sludges at one location in Germany but no applications are reported in Canada.

4.6 Effluent Stability

The stability of effluents from mining operations should be such that no adverse chemical or biological conversion of the compounds contained in the effluents will occur in the receiving environment. The two basic sources of effluent instability are thiosalts and milling reagents.

4.6.1 Thiosalts

The origin of thiosalts in mining effluents is described in Section 3. The impact of these materials on ambient water quality can be pronounced. Biochemical oxidation of thiosalts with various species of *Thiooxidans* bacteria in the receiving stream results in the formation of sulphuric acid and consequent pH depression. Although the manifestations of this phenomenon have been recognized for a long time, the cause has been established only during the last few years. Recent evaluations indicate that the problem is much more widespread than hitherto suspected. Three basic approaches have been advocated.

(a) Biochemical Oxidation

Bacterial action by a group of autotrophic aerobic bacteria can convert sulphur and its reduced compounds to sulphate. Table 7 indicates several species and their characteristics. Although some recent development work has been undertaken with the bacterium *Thiobacillus thioparus*, most data are available for *Thiobacillus thiooxidans*. The properties of the latter species are considered further.

The optimum conditions for bacterial oxidation are a pH of 3.5 and a temperature of 35°C, in the presence of adequate nutrient supply, oxygen etc. Both completely stirred tank and fixed film reactors are capable of providing the necessary process conditions as described in Section 4.2.2.

A CSTR design has been proposed by Schmidt (7) which incorporates a residence period of six days and is capable of completely oxidizing 1000 mg/l of thiosalts. This would utilize oxygen transfer rates of 5,700 lb/thousand gallons*. If such a process design were to be applied to Canadian mining conditions it would necessitate an outside lagoon or aeration basin which would operate at temperatures of near 0°C in the winter months. The reaction rate of the bacterial oxidation process tends to zero under these conditions and thus would be incapable of providing effluent stabilization in a practicable manner. Field data have confirmed this.

---

* Unless otherwise noted, gallons referred to in this report are imperial gallons.

TABLE 7. CHARACTERISTICS OF THE *THIOBACILLI* (7)

Name	Substrates Utilized Other than Thiosulphate	pH Characteristic	Remarks
T. thiooxidans	Sulphur Tetrathionate	Optimum pH 2.0 to 3.0 Range 1.0 to 6.0	Acidophilic; oxidizes thiosulphate rapidly to sulphate.
T. ferrooxidans	Ferrous iron Sulphur Trithionate Tetrathionate	Optimum pH near 3.5 Range 2 to 6	Acidophilic; unable to use sulphur rapidly. Optimum pH for oxidation of sulphur compounds is apparently pH 4 to 5.
T. concretivorus	Similar to *T. Thiooxidans* but differs principally in that it can use both ammonia and nitrate.		
T. thioparus	Sulphur Trithionate Tetrathionate Dithionate	Optimum pH near neutrality	Oxidation of substrate causes the medium to become acid.
T. denitrificans	Sulphur	Optimum pH near neutrality	Under anaerobic conditions uses nitrate as a terminal respiratory electron acceptor.
	Cultivated aerobically this bacterium is indistinguishable from *T. thioparus*.		
T. thiocyanoxidans	Thiocyanate Sulphur Sulphide	Optimum pH near neutrality (pH 6.8 to 7.6	Produces acid, oxidizes thiosulphate rapidly.
T. novellus	Various organics	Optimum pH near neutrality	Grows slowly, produces acid. Of all the above *thiobacilli* this is not an obligate autotroph but a facultative autotroph.

Note: All the *thiobacilli* oxidize thiosulphate to sulphate although the precise pathways have not yet been agreed upon.

Fixed film reactors show the same trends in oxidation kinetics but, due to their higher microbial population, exhibit faster and more complete reaction per unit reactor volume. These reactors are at the developmental stage and possess a high potential for in-plant treatment of warm streams containing high concentrations of thiosalts. Recent data have indicated that the oxidation reaction is now always carried through to the sulphate, and that intermediate oxidation products of the polythionate class may be present in significant quantities in process effluents. The causes and significance of this have not been established.

It must be emphasized that, while thiosalts may be found in many mining wastes in sulphidic areas, the concentrations may not be sufficiently high to warrant the installation of specific treatment operations to stabilize them. In many cases, the oxidation provided by normal retention times in a tailings pond may be sufficient without seriously lowering the pH in the system due to thiosalt oxidation. While such removal rates may be reduced during the winter months, it must also be borne in mind that the rate of biological oxidation of the residuals in the receiving streams will also be at a low level and the impact of small thiosalt residuals in such cases may not be significant.

(b) Chemical Oxidation

The chemical oxidation of thiosalts may be achieved through the use of chlorine, ozone, sodium chlorate, sodium hypochlorite and hydrogen peroxide. A cost analysis (see Section 5.4.6) indicates that oxidation using chlorine and ozone is most feasible although more expensive than bacterial means. It is worthwhile noting that the oxidation of thiosulphate by atmospheric oxidation is theoretically possible. Some evidence suggests that the catalytic influence of cobalt, nickel salts etc. may be dominant. Unfortunately, this process has not yet been successfully demonstrated.

The following equations have been proposed to describe the oxidation of thiosalts by chlorine and ozone.

Chlorine:

$$S_2O_3^{=} + 4Cl_2 + 5H_2O \rightarrow 2SO_4^{=} + 10H^+ + 8Cl^- \qquad (19)$$

Ozone:

either $2S_2O_3^{=} + 5O_3 + 2H_2O \rightarrow 4SO_4^{=} + 7/2O_2 + 4H^+$ (20)

or $5S_2O_3^{=} + 2O_3 + 7O_2 + 5H_2O \rightarrow 10SO_4^{=} + 10H^+$ (21)

All chemical and biological oxidation processes for thiosalts will result in acid formation and reductions in the pH of the process liquor. This may be of advantage through the precipitation of elemental sulphur.

$S_2O_3^{=} \rightarrow SO_3^{=} + S$ (slow) (22)

$SO_3^{=} + \frac{1}{2}O_2 \rightarrow SO_4^{=}$ (fast) (23)

$6H^+ + 5S_2O_3^{=} \rightarrow 2S_5O_6^{=} + 3H_2O$ (24)

Equations (22) and (23) indicate that substantial effluent stabilization may be expected through sulphur precipitation under acid conditions. At pH 3 up to 80% yield as elemental sulphur has been reported. Equation (24) indicates that higher thionates, probably in the form of polythionates and sulphurous acid, are formed. Thus, after complete precipitation of sulphur, residual concentrations of polythionates will exist which may require stabilization.

It may be concluded that both chemical and biological oxidation processes will be influenced by the dissociation of thiosalts under acid conditions.

(c) Addition of Buffer Solutions

The addition of sodium bicarbonate, soda ash, lime or other chemical buffers to the effluent stream provides a possible means of counteracting acid generation by thiosalt oxidation in the receiving stream. Costs, which are summarized in Section 4.1.2, are relatively high and the concept of applying chemical treatment in the receiving stream is not encouraged.

4.7 Process Reagent Stabilization

Although oxidizable organic process reagents are frequently inherently toxic materials (see Section 3.2.1) water quality problems are rarely attributed to this source. The majority of these reagents are subject to biological and/or chemical degradation under the conditions which exist in the tailings impoundment. A 30 day theoretical hydraulic

retention period is generally provided in the pool section of the tailings impoundment and it is inferred that this is sufficient for degradation to occur. In the event that a nondegradable toxic reagent is encountered, the use of a degradable alternative should be encouraged.

In certain instances, the hydrophic characteristics of many reagents may result in the formation of a monomolecular layer on the surface of the tailings pond. This may skim rapidly over the surface and report in the overflow. The provision of baffles and the use of submerged decant weirs can counteract this problem.

It should be noted that the breakdown products of nitrogen and phosphorus containing reagents may enrich the receiving stream and result in symptoms of eutrophication. Phosphates may be precipitated by the use of lime or limestone under alkaline conditions and, where acid conditions are being counteracted by these materials, no additional treatment is generally necessary.

4.8 Radium Removal

Uranium is extracted by leaching processes of two types. Acid leaching is used in the Elliot Lake District, while carbonate leaching is employed at Eldorado because of the high natural carbonate level in the gangue. In most operatins the mine water is directed to the mill for removal of dissolved uranium and is subsequently discharged as part of the ion exchange barren solution.

The liquid barren is recombined with the washed filter cake and discharged as mill tailings. Carbonate leach mills require no additional pH adjustment since the net discharge is at pH 8-9. The acid leach tailings are neutralized with lime or a limestone-lime combination and discharged at a pH of 8-10. Since the solid tailings may generate acid, it is desirable to have excess limestone available as a buffering agent. Effluents at pH 8-10 contain very little heavy metals (after sedimentation of hydroxides) and also contain reduced levels of Ra 226 after neutralization, typically from 400-800 pCi/l. The Ra 226 in the barren solution ranges from 3000-4000 pCi/l.

Radium is removed by co-precipitation with $BaSO_4$ by adding $BaCl_2$ to the effluent in the presence of excess sulphate (typically 0.01

to 0.1 lb/ton wastewater).

$$BaCl_2 + Ra^{++} + 2SO_4^{=} \rightarrow 2Cl^- + BaSO_4 \cdot RaSO_4 \qquad (25)$$

The treatment does not remove Ra effectively if the initial suspended solids are high since barium displaces radium from the solids. The co-precipitate settles slowly and adequate lagoons are needed to reach acceptable levels in the final effluent. The sludge formed may also be unstable if the sulphate level decreases to the point where $BaSO_4$ redissolves. A low input level of Ra 226 to the $BaCl_2$ system appears to be beneficial but this result has not been specifically confirmed.

The level of Ra 226 achieved in the final effluents from the various uranium mines varies somewhat because of minor differences in treatment practice and, in particular, because of variations in the sizes of the settling lagoons used. It is difficult, however, to identify specific cause and effect relationships between the effluent levels and the various treatment parameters since there are only three case studies available in Canada at this time (23).

A detailed study and review of the data available was conducted by the Radioactivity Expert Group as a subgroup of the Mining Regulations Task Force (23). This study showed that, using data for filtered samples (3 μ filter), a monthly average level of 10 pCi/l Ra 226 could be achieved using best practicable technology.

4.9 Suspended Solids

The most obvious environmental concern of a mining operation is to eliminate the discharge of tailings into the environment. This can be achieved through the use of an appropriately designed and operated tailings impoundment area. Canadian practice in this regard is considered in Section 5.3.

Although settling rates for the tailings may be measured and used as a process design consideration, this is generally not the controlling factor dictating tailings pond design. Other considerations, such as reagent stabilization requirements, decant design, topography, etc., are usually limiting factors. This results in substantial safety margins for the settling requirements. In those instances where solids carry-over is observed, physical modifications to the side to eliminate

possible short circuiting effects, and to alter the manner of tailings deposition and the depth of the stilling basin at the decant structure, are often able to rectify the situation. If necessary, this may be augmented by improving the settling characteristics through pH adjustment or the addition of flocculating agents.

4.10 Untreated Contaminants Present in Mining Effluents

As we increase our appreciation of the conditions necessary to sustain or improve our environment, we develop a progressively more conservative approach to the allowable discharge of contaminants. In the past, crude observations of parameters such as fish mortality guided the setting of pollution control requirements. The increased awareness of sublethal effects and synergism alert one to the harmful effects of substances that were previously considered completely harmless or were not even known to be present in the effluents from mining operations. Between the identification of a problem and the development of a solution there is always a delay. When the problem is in the field of water pollution abatement from an industrial source, the onus is upon the industry to develop practicable solutions for application to that particular sector or specific location.

The materials listed below are found in mining effluents. They do not occur universally and even when they do occur it is not suggested that they automatically constitute a problem.

The one common characteristic that they possess is that there is no generally accepted means of providing treatment for them as they appear in mining effluents. The alternative approach to that of developing treatment processes is to make in-plant or process modifications to eliminate the contaminant at source.

Typical contaminants are:

(a) sulphates
(b) ammonia
(c) nitrate
(d) hardness
(e) chlorides

LIME/LIMESTONE AMD NEUTRALIZATION PLANTS

Examples of operations visited or reviewed by Randol International Ltd. during this investigation where limestone or lime were used to treat acid mine drainage were:

Lime

1) Falconbridge Sudbury Operations, Falconbridge, Ontario
2) INCO Sudbury Operations, Ontario
3) St. Joe Minerals, Balmat Operations, New York State
4) Falconbridge Onaping Operations, Strathcona Mill, Ontario
5) Kidd Creek Mines Ltd., Kidd Creek Mine, Ontario
6) Kidd Creek Mines Ltd. Timmins Mill Tailings Decant

Limestone

1) Falconbridge Onaping Operations, Moose Lake, pH adjustment.
2) Rössing Uranium Ltd.,passive neutralization of seepage.
3) Schullsburg Mine, passive neutralization by dolomitic limestone with disastrous results.
4) Gold Field of South Africa Ltd., Greenside Colliery, South Africa (abandoned due to lack of success).
5) Limestone column tests by Noranda Mines Ltd. at Heathe Steel Mine, New Brunswick.
6) U.S. Bureau of Mines, limestone neutralization process tests 1967-68 and process demo, 1982.
7) Pennsylvania Bureau of Abandoned Mines, reclamation test.

Interesting variations on the theme of lime neutralization, precipitation, and solid/liquid separation include the use of dissolved air flotation for flotation and also the Dravo Lectroclear flotation system. The latter is installed at an expensive but efficient AMD treatment plant at AMAX Molybdenum Division's Mount Emmons operations at Crested Butte, Colorado, which is described in detail in a trip report included in Appendix I.

Falconbridge Sudbury Operations

The Falconbridge integrated mine, mill, smelter, and refinery complex at Falconbridge, Ontario, has achieved remarkable improvement in effluent and environmental quality. Much of the improvement can be attributed to a change in some of the pyrometallurgical processes and also to the systems approach adopted in managing and treating water in a macro recycling system.

It would not be proper to refer to the lime neutralization plant at Falconbridge without referring to this exceptional example of what can be achieved by applying a systems approach. The Falconbridge operations at Falconbridge, Ontario, and at Onaping, Ontario, are included as trip reports in Appendix I. In addition, excellent accounts of the wastewater treatment system at Falconbridge, Ontario, are provided by MICHELUTTI (1981) and NORMAN and MICHELUTTI (?).

Here, only some details germaine to lime neutralization are summarized to illustrate an example where conventional lime neutralization works particularly well.

A new tailings area and wastewater treatment system was put into operation at the end of 1978 at a cost of around C$3 million. After the first two years of operation, the following results had been achieved.

1. Integrated air pollution control measures at the smelter complex reduced fallout contribution to metal levels in Falconbridge effluents.

2. The tailings and the polishing ponds required 13 weeks to fill their operating levels for a total of 368×10^6 Imperial gallons (1.75 million m^3).

3. The settling pond downstream of the neutralization plant has a retention time of approximately 15 days at 2,900 Igpm <u>inflow</u> (19,000 m^3/d) with a volume of 63×10^6 Imperial gallons (286,373 m^3). The settling pond, which formerly was barren wasteland, sprang to life on becoming flooded with shallow alkaline water. The prolific plant life and algae in the pond acts as a high surface area polishing pond to remove whatever metal hydroxide particles do not settle on their own.

   The inflow is made up of 1566 Igpm: (10,000 m^3/d) tailings and process water; 500 Igpm (3,300 m^3/d) groundwater; 742 Igpm (5,000 m^3/d) precipitation.

4. The average flow leaving the treatment plant during 1979-80 was 2,511 Igpm (16,000 m^3/d). The total flow discharged as a final effluent to Coniston Creek was 5,480 Igpm (36,000 m^3/d) during the same period.

5. Sulfate concentrations decrease with distance from the source.

6. pH values are 3.5 during the summer and 6.5 during the winter in the tailings ponds. This is due to the varying oxidation rates of sulfo-salts by chemical and/or bacterial action.

7. Nickel concentration in the wastewater inflow dropped considerably from 1979 to 1980 (0.7 ppm to 0.1 ppm).

8. Dissolved nickel concentrations increase downstream from the inflow as well as downstream from the treatment plant. A possible explanation was solution pickup of nickel from the bog area, the area having formerly been exposed to airborne fallout from the smelter-roaster. Nickel in the bog is not perfectly "fixed" at the operating pH.

9. The suspended solids two-year average leaving the settling pond was 5.8 ppm indicating that a clarifier is not warranted. It was estimated that it would require 65 years to accumulate 1" of sludge in the settling pond at the 1981 rate of deposition.

10. pH depression caused by organic acids in the bog area downsteam of the treatment plant was corrected by discharging excess lime.

11. The treatment plant treated 3.6×10^6 lgpd (16,400 m^3/d) at a cost of 4.6 cents per 1000 gallons \$0.01/m^3 during 1980. On average, 0.84 tons hydrated lime/d were consumed in 1980.

12. Treated alkaline wastewater has resulted in a rapid colonization of the denuded bog by aquatic plants and wildlife. As a result, the area is now a designated "Conservation Area."

13. It is concluded that conventional lime neutralization followed by polishing in a large shallow settling pond filled with aquatic plants with a very high surface area can represent an extremely economical way to adjust the pH of AMD and remove dissolved metals. There remain some questions as to nickel removal at the operating pH.

Additional information is available in the excellent papers on the subject referred to above, the trip report included in Appendix I or from:

Wastewater Treatment System at
Falconbridge Ontario

East Mine Treatment Plant - Cost Analysis

(to nearest $100.00 Canadian)

	1979	1980
Labour	$ 3,900	$ 200
Supervision	$ 11,700	$ 11,500
Lime	$ 48,100	$ 23,700
Polyelectrolyte	$ 2,200	0
Building Repairs	$ 1,000	$ 800
Equipment Repairs	$ 12,000	$ 6,800
Instrumentation Repairs	$ 23,900	$ 17,100
Supplies	$ 1,800	0
TOTAL	$104,600	$ 60,100

At a flow rate of 3.6 M.G.P.D. the 1980 costs were 4.6¢ per 1,000 gallons treated.

INCO SUDBURY OPERATIONS

INCO LTD. produces 110,000 tpa nickel at Sudbury at their currently reduced capacity. Plant capacity was reduced because of environmental restriction mainly on SO_2 emmissions. INCO LTD. in Ontario operates three lime-settle plants to treat acid water. The one at Copper Cliff is part of a massive integrated water management complex.

Plant Capacity

Plant	Year Erected	Capacity	Capital Cost
Nolen Creek	1975	6.3 mm Igpd 28,600 m^3/d	C$0.69 Million
Copper Cliff	1975	60 mm Igpd 272,000 m^3/d	C$4.1 Million
Port Colbourne	1981	9 mm Igpd 41,000 m^3/d	C$5.1 Million

Plant Throughput

INCO, at the Copper Cliff plant, treats 86,000-160,000 m^3/d water from tailings seepage, decant, and runoff.

Plant Performance

	Raw Feed Water	Effluent After Treatment
pH	4.4	10.2
Cu	0.8 ppm	0.1 ppm
Ni	9.5	0.1
Fe	13.4	0.35
S/S	14.0	2.7

Sludge Properties

The sludge, at around 2% solids of which 3-4% is nickel and 0.2% Cu, is mixed with tailings in a sump pump and discharged back to the huge tailings area.

Treatment Plant Description

Incoming effluent, which includes decant solution from the main active tailings impoundment and runoff, arrives via an open ditch to a raw water well equipped with three submersible pumps, each with a capacity of 15,000 gpm.

Lime is added directly to the ditch about 150-200 feet upstream from the plant, and a considerable amount of precipitation occurs in the ditch. In the wintertime warm sewage is added to the raw water well which tends to reduce frazzle ice.

The water at pH 10 is next pumped to two EIMCO reactor clarifiers. A liquid polymer Aichem 8C26 is added just before the neutralized solution flow reaches the thickeners. The reactor clarifiers have a diameter of 135'Ø with 22' vertical sidewalls and have a capacity of 2.5 mm U.S. gallons, i.e., 9,500 m^3.

Overflow solution from the reactor clarifiers is released to the Copper Cliff stream by gravity flow. Sludge at 2% solids, of which 3-4% is Ni, gets discarded to the tailings area after being blended with the tailings. Each sludge pump can handle 450 gpm (3000 m^3/d).

The INCO water treatment plant uses EIMCO reactor clarifiers operated with a sludge blanket and rakes. To facilitate flow of solution in winter they have been designed with radial launders submerged 3 feet below the surface so that they will operate even when the surface is frozen.

Sludge Stability

The solubility of nickel reaches a minimum of around 0.075 ±0.05 ppm. Raising the pH to 10.5 increases the theoretical solubility of Ni to 0.075 + 0.05 ppm. The sludge is relatively soluble and can redissolve in the tailings dam, however the soluble Ni sludge in the precipitate is low; it is said to be lower than in the tailings themselves.

Cost of Water Treatment

C$0.30/1000g = C$0.07/m^3.

Lime Precipitation: Balmat Mine Location

The Balmat Mine location of ST. JOE MINERALS COMPANY in New York State operates an extensive complex of mines and a mill. By rerouting their underground minewater through the Edwards Mill as process water, a significant reduction in suspended solids and dissolved metals was affected as described by REILLY (1979) inserted below. Minewater is already at pH 7-8 due to the carbonate rock types.

Additional inquiries can be addressed to:

The following summary should be read in conjunction with the summary on passive AMD polishing at the Balmat Mine location in the next section of this chapter.

MINE WATER TREATMENT SYSTEM AT THE BALMAT MINE LOCATION

J. G. REILLY
ST. JOE ZINC COMPANY
MINING DIVISION
BALMAT, NEW YORK

SUMMARY

A system for reducing the concentration of dissolved metals in mine water effluents was installed and is operating successfully. The basis for this water treatment system is lime/sedimentation, and the design concept was to minimize capital and operating costs by utilizing existing process streams and facilities. This was accomplished by rerouting the waters from the underground mines to the mill for use as process water and by subsequent treatment in the existing tailings lagooning system.

INTRODUCTION

The Mining Division operates mining and milling facilities in St. Lawrence County, New York State. The final product is zinc mineral concentrate and a by-product lead mineral concentrate. The Balmat operations consists principally of #2, #3, and #4 Mines and the #4 Mill. The Mill presently processes Balmat ore as well as ore trucked in from the Edwards Mine and the Hyatt Mine, respectively eleven miles and seven miles in distance from the Balmat operation.

BACKGROUND

The present Balmat Mine water treatment system was developed for the purpose of reducing the dissolved metal content of discharged waters to presently acceptable standards.

In the period following the passage of the Clean Water Act of 1972 the Mining Division began a monitoring program to determine the characteristics of the various discharge waters. In 1974 draft discharge permits and compliance schedules were issued by the EPA. For discharges from mining facilities it was evident that "clean" in appearance would no longer constitute the norm for acceptable discharge quality.

The monitoring program indicated that the effluent from the existing tailings lagooning system was generally satisfactory under the new standards, but that the mine water discharges contained unacceptable concentrations of dissolved metals.

DEVELOPMENT OF THE MINE WATER TREATMENT SYSTEM

Laboratory testing of the discharged waters from the Balmat mines indicated that the lime/sedimentation process, which was specified by the EPA as the Best Practical Technology (BPT), could produce an effluent of acceptable quality to meet the new standards. However, the traditional concept of end-of-pipe treatment system for each mine discharge was economically discouraging when considering the cost elements for multiple installations, buildings and hardware, sludge disposal problems, and daily operating costs (chemicals, labor, maintenance, winter heating, etc.).

As an alternative to the traditional water treatment system, the plan developed and instituted for the Balmat mining complex was oriented toward making the greatest possible use of existing facilities and the minimum increase in additional operating costs.

Basically, the concept of the plan was to gather all of the mine waters together at #4 shaft, to pump to the surface, to re-use the mine water as mill process water which would provide the exposure to high lime concentration (pH 10 to 11) for precipitation of heavy metals during passage through the flotation circuit. The resulting precipitated heavy metals would then follow the path of the tailings slurry for sedimentation in the tailings treatment lagooning system. It was believed that the existing good quality of the discharge effluent from the tailings system would not be adversely affected by the additional heavy metal precipitates.

Simplified flow schematics are shown on Figures 1 and 2 for the original and for the new systems.

INSTALLATION AND OPERATION

Rock excavation began in 1975 for the new pumping station on the 1300 level at #4 Mine shaft. During the next two years the pump station (20,000 cubic feet) and the sump (150,000 cubic feet) were excavated and outfitted. The sump was designed to contain the normal expected inflow of 500 GPM for 14 to 20 hours in the event of power failure. The equipment installed at this underground pump station included three Peerless 12 stage pumps, each at 250 HP and 500 GPM, and the accompanying electrical transformers, distribution and monitoring gear. The installation began partial operation in October, 1977.

For #2 Mine, the mine water (nominally 100 GPM) was re-routed to the new #4 shaft pump station by installing 4400 feet of pipeline in the existing 1300 level drift connecting the #2 and #4 Mines. Two low head pumps were installed at the existing #2 Mine 1300 level pump and connected to the new line. This portion of the system became operational in October, 1977, at which time the existing #2 Mine pumps (to surface discharge) were permanently shut down.

The re-routing of the #3 Mine water (nominally 400 GPM) to the #4 shaft 1300 level pump station was more difficult, because the lowest level at #3 Mine is the 900 level and a new water passage route was required and was established as follows:

A ten foot wide by ten foot high drift was driven for 2000 feet on the 1300 level from the #4 Mine to a location under the #3 Mine 900 level, and several bore holes were then drilled from the #3 Mine 900 level to intersect the new 1300 level drift. Several sources of water intruding into the #3 Mine were found not to be carriers of dissolved metals, and this water was segregated for continued pumping from the #3 Mine 900 level pumps to the surface for direct discharge. A number of problems delayed the #3 Mine portion of the system until start-up in March, 1978.

The surface installations for the mine water treatment system began in the Fall of 1976 by starting the excavation for the three-acre surge pond whose purpose was for receiving the mine water and for mill water supply. This pond, located in a depression adjacent to #4 Mill, was also designed to intercept floor wash from the mill as well as run off from the ore storage area, an improvement which eliminated potentially troublesome discharges to the plant storm sewer system. These surface facilities became operational in October, 1977.

The surface handling of mine water was designed for flexibilities of operation so that mine water pumped could be either stored in the pond or diverted directly (after liming) to the mill tailings system. The system's storage capability also provided the scheduling flexibility so that mine pumping can avoid electric power peaking.

A simplified flow schematic is shown at Figure 2.

OPERATIONAL RESULTS

The following observations are made as a result of the experience to date with the Balmat mine water treatment system:

Based on present standards, acceptable quality discharge effluents can be achieved at this location without the need for traditional end-of-pipe treatment facilities.

Concurrent sedimentation of tailings particles along with the flocs of precipitated heavy metals is believed to exhibit a superior performance to the sedimentation characteristics of the flocs by themselves.

Operating costs have been minimized by making use of the processing streams and the equipment already functioning.

SIMPLIFIED WATER FLOW CHARTS

FIGURE 1. BEFORE
MINE WATER TREATMENT SYSTEM.

FIGURE 2. AFTER
MINE WATER TREATMENT SYSTEM

JGR 11/6/77

Two former direct discharges to the surface waters have been eliminated completely and another one has been significantly reduced.

A substantial reduction has been made in the quantity of fresh water required for the milling process with no apparent detrimental change in the mill metallurgy.

Table I shows the quality of the discharged water resulting from the completed water treatment system as compared to the former mode of operation.

Table II compares the discharge loading to surface waters for suspended solids and for zinc, indicating reduction of 81% and 92%, respectively, over the former system.

AFFECT OF CO_2 AND Al^{3+} ON LIME CONSUMPTION

LIMESTONE NEUTRALIZATION: FALCONBRIDGE STRATHCONA MILL

The Falconbridge Strathcona Mill is located at Strathcona, Ontario, a thirty-minute car drive north of Sudbury. A more accurate company-corrected description is included in Appendix I. Through contact with tailings and AMD from the Fecunis Mine and now closed Fecunis Mill, the water in Fecunis Lake in 1984 contains 14 ppm-15 ppm Ni in solution. This water would normally drain into Moose Lake and then to the effluent discharge point for the system.

Moose Lake water was used as process water for the Strathcona Mill. However, since the Moose Lake water is treated with limestone, it contains a high level of dissolved carbonates which consumes flotation reagents.

Rather than the former arrangement of using Moose Lake water in the Strathcona Mill which then is decanted back to Moose Lake after being discharged with Strathcona Mill tailings, and rather than discharging Fecunis Lake water to Moose Lake where it adds significantly to the nickel load, Falconbridge now draws nickel contaminated millwater for the Strathcona Mill from Fecunis Lake. In this way, the nickel in this water is precipitated at pH 10 onto Strathcona Mill tailings which decant to the Moose Lake at less than 1 ppm Ni. Since one of INCO's mines in the area contributes to AMD generation in Fecunis Lake, they contribute a payment to Falconbridge for treating their share of the water.

In the future, the south end wall of Fecunis Lake will be raised by a 5 foot dam causing the lake drainage to flow in reverse toward a new offtake for Strathcona Mill water which will allow water to be taken from the lake immediately adjacent to the mill which will reduce pumping costs significantly.

This is an example of the benefits achievable when a systems approach is employed.

NEUTRALIZATION AND DISSOLVED AIR FLOTATION (DAF)

BOSMAN (1983) pointed out that in some cases, even where HDS can yield a dense sludge, say 39% solids, HDS may still not be the most practical approach. One example of this was AMD from a pyrite mine which, when neutralized, contained only 100-200 mg/l suspended precipitate--a very low solids load. Although HDS achieved good densification, there are perhaps simpler ways to achieve clarification and low sludge volumes.

BOSMAN pointed out that because of the low settling rates of iron hydroxide particles, sometimes less than 1 m/h, solids-liquid separation by means of flotation is a logical alternative for water with such low solids loadings as mentioned above.

BOSMAN considers dissolved air flotation (DAF), electroflotation, and dispersed air flotation to be potential candidates for this job. RAMIREZ and RAMADORAI (1980) showed how molybdenum co-precipitated with ferric or other trivalent ions from AMD could be efficiently removed using DAF. DAF is discussed in greater detail in Chapter 12.

LIMESTONE NEUTRALIZATION

Because of limestone's general local availability and lower cost, there would be a potential economic advantage in using it for neutralization of acidic effluents. If it is not in general use, however. The reasons for this are:

- Limestone is less effective than lime for acid neutralization. Assuming stoichiometric consumption, limestone can only neutralize 57% of the acid that the same weight of lime can neutralize.

- Stoichiometry of limestone neutralization is not as complete as when lime is used. This is because the limestone particles used become coated by a passivating coating of $CaSO_4$ and other precipitates including silica (possibly as calcium silicate).

- Limestone neutralization reactions are not as fast as lime neutralization.

- Limestone addition can raise the pH to no more than 7-8 which is too low to reach the minimum solubility of many base metals which require pH up to 10.

In some parts of the world, limestone is much less expensive than lime. For example, in parts of northern Ontario, limestone may be locally available whereas lime must be trucked or railed several hundred miles.

Considerable development and testwork has been undertaken to find ways to use limestone for AMD treatment. Work in the late 1960's by the U.S. BM is described by MIHOK, et al. (1968), and DEUL and MIHOK (1967) inserted below.

Advantages of limestone, other than cost in certain circumstances, are that it is safer and sightlier to handle and that under certain circumstances it may be particularly appropriate for passive systems, i.e., for treatment of acid mine drainage at worked out mines where economics do not dictate a conventional lime neutralization-oxidation-settle and clarification system such as several of those discussed above. The U.S. Bureau of Mines in particular has been very active in developing experimental and demonstration systems for use at small AMD flow sites, particularly from abandoned coal mining waste dumps and workings where iron is the most common metal contaminant in the AMD effluent. Limestone precipitated sludges often have a higher solids density than lime precipitated

sludges, albeit only around 2-3% solids. The following are accounts of limestone neutralization plants encountered during this investigation.

McDONALD and GRANDT (1981) of the PEABODY COAL COMPANY found that a combination of limestone-lime process has cost advantages with improved effluent quality and sludge settling characteristics. A full-scale neutralization plant was operated to determine the effect of retention times, sludge recirculation flow patterns, and operating pH using limestone and lime separately and in combination. The operation found that the combination of limestone and lime treatment with sludge recirculation in both treatment steps is the most economical. More details can be obtained in EPA-600/7-81-033 (PB81-172645) obtainable from the National Technical Information Service, Springfield, Virginia.

ENOXY COAL, INC., BUCKHANNON, WEST VIRGINIA

In order to inhibit AMD in parts of the West Virginia coal region, several companies, including ENOXY COAL, INC., mix a carbonate waste rock with their coal spoil. High alkalinity carbonate rock effectively prevents the pH from dropping and also removes iron from runoff and seepage water. However, as iron is precipitated, manganese present in the carbonate rock goes into solution and reaches levels of 30-130 ppm which is well over the allowable effluent limits.

Removal of manganese needs a pH over 10, and it is very difficult to remove in the absence of iron. In this case Mn:Fe ratios of 10:1 are typical. A final pH adjustment would then be needed to bring pH down to dischargeable limits 6-9.

ENOXY COAL, INC. has explored several avenues in the search for a practical way to remove manganese:

ENOXY COAL, INC.
Post Office Box 710
Buckhannon, WV 26201
(304) 472-9274
Allan Meek

To date, they had found no practical way for manganese removal. Also, since no environmental reasons have been found for manganese removal, it is possible that the limit on manganese may have been placed there originally because it is a symptom of AMD requiring treatment to remove other metals. Manganese is a problem in potable water because of the black marks it leaves on porcelain, but evidence of environmental damage has yet to be found. A movement is afoot to persuade regulators to change the rules on manganese. (Note: Stewart Herman of BETHLEHEM STEEL indicated at the RANDOL Workshop that the HDS process can be adapted for solutions with low Fe:Mn ratio.)

In the above case, the effective inhibition of AMD by limestone addition to coal spoil, itself resulted in a new effluent problem that is even more difficult to solve, namely soluble manganese.

FALCONBRIDGE LTD., ONAPING, ONTARIO

At Falconbridge's mine-mill complex at Onaping, Ontario, a limestone neutralization plant was installed to treat a flow varying between 30,000 igpm (200,000 m^3/d) during spring runoff and 6000 igpm (40,000 m^3/d) during the driest part of the summer.

Limestone can acheive a pH adjustment approaching pH 7, and the Onaping plant is part of a comprehensive water management and AMD abatement program adopted by Falconbridge and described in Appendix I.

The limestone neutralization plant is described by RIVETT and OKO in the following Deco Trefoil report dated 1972. There has been little change in the plant since then.

The latest annual operating cost figures which are for 1981 are as follows for the limestone neutralization plant.

Labor	$25,500
Fringes	11,000
Supplies	35,000
Electricity	7,500
Maintenance	17,000
	$95,000

1984 operating costs are budgeted at C$108,000 for this plant which works out to C$0.03 per m^3 of water treated (C$0.14 per 1000 I gallons).

Tailings Disposal, Generation of Acidity from Pyrrhotite and Limestone Neutralization of Waste water at Falconbridge's Onaping Mines

By L. S. RIVETT and U. M. OKO, Falconbridge Nickel Mines Limited

L. S. RIVETT was born in Haileybury, Ontario. He received his engineering degree in chemical engineering at McGill in 1935, and joined Siscoe Gold Mines, northern Quebec. In 1937, he joined Falconbridge Nickel Mines Ltd., where he became mill engineer in charge of experimentation. Between 1940 and 1946, he worked for C-I-I in Hamilton and Copper Cliff, Ontario.

Mr. Rivett rejoined Falconbridge Nickel Mines in 1946 and was steadily promoted to his present position of general superintendent of the Falconbridge Area. He currently lives in Falconbridge, Ontario.

L. S. RIVETT

U. M. OKO

URIEL M. OKO was born in Israel and moved to Canada in 1955. He received his Bachelor of Engineering from McGill in 1961. In 1964, after three years of foundry engineering in Montreal, Quebec and Belleville, Ontario, he returned to McGill for his Master in Mineral Dressing, work which he performed under the direction of Dr. T. Salman in the Metallurgical Engineering Department. In 1969 he received his Ph.D. from the University of Missouri. The research he conducted there involved mine-water pollution abatement.

Dr. Oko joined the Falconbridge organization in 1969, where he is now industrial wastes control engineer in charge of water pollution abatement, Sudbury operations.

FIGURE 1
The Moose Lake System[1]

Introduction

Until recently, the only apparent water pollution problem that required attention in the minerals industry was the separation of the suspended solids from the mine and mill waste effluents. Operators were conditioned to this requirement and generally did an acceptable job.

Over the past few years, however, the situation has altered radically as a result of the considerable increase in our understanding of the effect that various trace elements can have on the ecology of stream systems. Naturally, legislation governing water pollution control has been strengthened to keep pace with the greater knowledge and understanding. In many cases, tailings disposal is now no longer a simple matter of a well-built dam and a clear overflow.

This paper describes special circumstances encountered by Falconbridge Nickel Mines Limited when bringing a large new mine and concentrator (Strathcona) into production.

The water pollution problem associated with the mining and treatment of sulphide ores that has to be resolved is essentially one of acid formation. If this could be eliminated, the problems of dissolved heavy metals and of sulphides would also virtually disappear. However, whenever water comes into contact with the sulphide mineral pyrrhotite that forms some 15 per cent of the Sudbury District ores, in the mining, grinding, flotation or other processing steps, small amounts of sulphur are dissolved to form sulphur compounds that oxidize eventually to sulphuric acid. The rates of dissolution depend on a variety of conditions, but in general the reactions are slow.

The only available water supply for the Strathcona operation was Moose Lake[1], but this was insufficient for the requirement of 3,000 gallons per minute. In addition, the water in this lake had already become acidic (pH 3.7) as a result of an earlier concentrating operation at Fecunis. It was obvious that process water would have to be recirculated.

The solution adopted was to utilize part of the lake as both a reservoir and an ageing or oxidizing basin. A dam and spillway were constructed in order to introduce a continuous stream of finely ground limestone pulp to neutralize the acidity. The limestone neutralization unit was designed to operate continuously and unattended.

This system has operated satisfactorily over the past several years, producing good-quality neutral water at flow rates varying from 6,000 to 30,000 gallons per minute (spring runoff).

Source of Sulphuric Acid in the Lake Water

Falconbridge Nickel Mines Limited started using the Moose Lake watershed for a water supply and for the retention of tailings in 1955, when the Fecunis Lake mill was brought into production. The mill discharged its tailings into a dammed-off marsh which drained into Cranberry Lake (see Figure 1). To prevent suspended solids from reaching Moose Lake, a dam was constructed at the outlet of Cranberry Lake.

During the ten-year period that the Fecunis Lake concentrator had been in operation, up to 1966, the water decanting from its tailings disposal area had resulted in the water of Moose Lake becoming appreciably acid. This is due to the fact that, during grinding and flotation operations in the concentrator, a small amount of sulphur from the mineral pyrrhotite dissolves in the water. The process seems to be independent of water temperature, but is accelerated at an alkaline pH which is normal in the Falconbridge flotation circuits. As a result, the water leaving a typical Falconbridge mill has a chemical oxygen demand (C.O.D.)[2] of approximately 50 parts per million (ppm). This is not a particularly high figure, but the products of oxidation, with the passage of time, generate sulphuric acid, which causes the pH of the water to decrease to levels that are toxic to aquatic life.

The dissolution process of sulphur from pyrrhotite, accelerated in an alkaline environment, is typical of that of other metal sulphides[3],[4]:

$$Fe_7S_8 + 20H^- \rightarrow 7FeS + S^= + H_2O + \tfrac{1}{2}O_2 \quad \ldots\ldots(1)$$

The kinetics of the oxidation of dissolved sulphide to sulphuric acid depend on many factors, such as sunlight, water temperature, pH and the presence of active sulphur-oxidizing bacteria[3],[6]. The intermediate products of oxidation, called polythionates, further oxidize to the ultimate product, sulphuric acid, which results in practically complete elimination of the C.O.D. in the water. Reaction (2) describes the oxidation of the unstable sulphide ion. This accounts for the presence of thiosulphate in the mill effluents.[7]

$$2S^= + 2O_2 + H_2O \rightarrow S_2O_3^= + OH \quad \ldots\ldots(2)$$

Polythionates, identified as $S_3O_6^=$, $S^=O_6$, (n, 4 to 8), are formed as shown below[8].

$$S_2O_3^= + H_2O + 4O \rightarrow 2SO_4^= + 2H^+ \quad \ldots\ldots(3)$$

$$nS_2O_3^= + (n-2)H_2O + 2(5-n)O \rightarrow 2S_nO_6^= + 2(n-2)OH^- \quad (4)$$

Pumphouse, slurry plant, limestone stockpile on banks of Moose Lake. The ½"x¼" limestone chips are wet ground to 90% mesh. The lime slurry is discharged at the rate of 200 g.p.m. over the Moose Lake Narrows Dam to blend with and neutralize the acid water.

and the ultimate oxidation to sulphuric acid is described as follows:

$$S_nO_6^{=} + (n-1)H_2O + (3n-5)O \rightarrow nSO_4^{=} + 2(n-1)H^{+} \quad (5)$$

resulting in the generation of hydrogen ions and a decline in the pH.

Neutralization

There being no known practical economic method of preventing the formation of the polythionates and subsequently sulphuric acid in the ore concentration and tailings disposal system, the only available solution to the problem is to neutralize the acid after it has been found.

In the system under consideration, this meant the neutralization of all the decant solutions from the Fecunis Lake and the Strathcona tailings disposal areas at a location where the sulphur compounds in these solutions had become completely oxidized to sulphuric acid. Of the neutralizing agents available, limestone was the most advantageous with respect to cost and ease of handling. Also, it had the advantage that an excess of limestone could be tolerated without raising the pH of the water above the acceptable limits. Caustic soda or lime would present major control problems and ammonia was unacceptable because of its fertilizing properties. The neutralizing action of limestone is described by equation (6).

$$CaCO_3 + H_2SO_4 \rightarrow CaSO_4 + CO_2 + H_2O \quad (6)$$

Choice of Tailing Impound for the Strathcona Concentrator

The Strathcona tailings disposal basin had to be large enough to contain an estimated 6,250,000 dry tons of tailings slimes, the quantity that would be produced over the 25-year expected life of the mine, keeping in mind that this disposal area might have to contain several times this amount, as there were distinct possibilities that additional major orebodies would be developed in this general area.

Containing a 25-year output of mine tailings can present a major problem. This was particularly so for Strathcona. The topography of the area is extremely rugged and unsuited for impounding. To further complicate the problem, the area is a checkerboard of mining claims, only part of which belong to Falconbridge. The removal of the sandy portion of the mill tailings for use as fill underground leaves a slime which is useless for dam construction. Thus, material for dam building has to be provided and in this immediate area was limited to small gravel deposits located around the periphery of the lake.

Of the eight areas which appeared worthy of consideration, the northwest arm of Moose Lake, an area of about 2,290,000 sq. ft., seemed to be most favorable. Impounding this area required a short dam, and therefore little gravel, and decant water from this site could be recycled back to the mill as process water, thus alleviating seasonal shortages. The estimated capacity of the impounding area was 139,288,000 cu. ft., adequate for 25 years, if a dam 35 ft. above the original water level were to be constructed at the outlet of the northwest arm.

The choice of this particular tailings disposal area fitted in very well with the over-all water treatment system proposed in that the tailing water effluent from both Fecunis Lake and Strathcona would flow into Moose Lake, which would provide the retention time necessary for the oxidation of the sulphur compounds to sulphuric acid and, by the judicious location of the water treatment facility, would not only insure that treated water would be discharged to the outflowing water course but also that the pumping installation providing water to the two concentrators would also be handling treated water.

Dam for the Strathcona Tailings Pond

The dam was designed to be built from gravel located in a small nearby deposit, using the Ontario Water Resources Commission (O.W.R.C.) specifica-

FIGURE 2—Layout of the Moose Lake neutralization plant and the cross sections of the dam across the lake narrows.

tions for slope and width. After approval had been obtained from the O.W.R.C. for the construction of the gravel dam, as much as possible of the sediment and vegetable material on the lake bottom at the narrows was removed with a drag line. For pockets of sediment that could not be reached readily by the drag line, explosive charges were used. A narrow dam was built first across the narrows and then widened to its full width. This sequence of construction is considered to be the best method of displacing any remaining bottom detritus and thus providing for best foundations.

In the initial construction stage, the dam base was built to its full final width and, at the same time, a concrete decant tower was built with provision for later extension as required.

Dam for Moose Lake

To insure that Moose Lake acted as an effective reservoir year 'round, including the relatively dry summer months, O.W.R.C. and the Ontario Department of Lands and Forests approval was obtained to construct a dam across the narrows near the south end of the lake to raise the water in the main body of Moose Lake by about 5 feet. This also permitted the use of a weir in which the limestone slurry could be mixed satisfactorily with the outflow water. A gravel dam was constructed, as shown in Figure 2.

Water at the Moose Lake System

The entire Moose Lake system has a watershed area estimated at 10 square miles and an average annual precipitation of 29.5 inches. The main body of the lake alone has an area of 26,200,000 sq. ft. and is about 50 ft. deep, equivalent to a storage capacity of some 8.1 x 10^{9} Imperial gallons. The annual outflow to the Onaping River amounts to about a third of this storage capacity, which, in other words, means that its retention time is about three years.

Table I summarizes the annual water balance for the lake, including the projected consumption of the Strathcona and Fecunis mills.

The lengthy retention time of the tailings water in Moose Lake allows for complete oxidation of the dissolved Polythionates to sulphuric acid, and the year-'round discharge, despite seasonal fluctuations in temperature and water runoff, has no C.O.D. A comparison between the water quality at the tailings pond outlets during the winter and the Moose Lake system outlet, before and after neutralization, is shown in Table II.

It is evident from Table II that the tailings pond effects essentially complete solid-liquid separation and that the decanted water, with a high C.O.D. is completely oxidized by the time it reaches the Moose Lake outlet. The table also shows that the use of limestone as a neutralizing agent does not greatly increase the dissolved solids content of the water and that the lower reaches of Moose Lake below the neutralization plant provide a settling basin for the precipitate formed by the limestone treatment.

TABLE I—Annual Water Balance for Moose Lake

	Volume in Imp. Gals.
Total Precipitation	4,210,000,000
Mill Effluents	2,290,000,000
Total Inflow	6,500,000,000
Evaporation and Percolation Losses	962,000,000
Total Water to be Neutralized	5,540,000,000
Water for Mills	2,290,000,000
Net Outflow to Onaping River	3,250,000,000

The concentration of polythionates is determined by noting the difference in the sulphate concentration in the water before and after oxidation. The oxidation of polythionates can be performed using conventional analytical procedures.[10],[11]

Moose Lake Neutralization Plant

The factors that were most important in the development of the best over-all plan were: (a) that the quality of water flowing out of the system should be acceptable to the Ontario Water Resources Commission[9]; (b) that the overflow from the Strathcona tailings disposal area should decant into Moose Lake; (c) that a water treatment facility be located so as to be able to treat the decant from both the Fecunis Lake and Strathcona tailings disposal areas; and (d) that the water treatment facility be located upstream from the pumphouse that would deliver the process water to the Fecunis Lake and Strathcona concentrators.

To effect neutralization, it was necessary to contact very large and variable water flows with relatively small amounts of limestone. This could only be achieved by funneling the water through a relatively narrow weir and using the turbulence as a means of mixing finely ground limestone with the water. The water flows varied from a high of 30,000 Imperial gallons per minute during the spring runoff to a low of about 6,000 Imperial gallons per minute during the driest part of the summer. For water with a pH of about 3, this indicated requirements of from 3.5 to about 10 tons of limestone per day.

The scheme finally adopted was to wet-grind limestone chips extremely fine, dilute the wet thick slurry and introduce it at a rate of 200 Imperial gallons per minute into the water overflowing the weir in the Moose Lake Narrows dam. The neutralization plant, shown in Figure 3, consists of a 50-ton limestone bin, a spiral feeder for a 4- by 6-ft. DENVER Ball Mill powered by a 40-hp motor, and a pumping arrangement for the limestone slurry, which is diluted in the wood-stave tank that receives the ball-mill discharge. Table III is a list of the plant equipment and the approximate cost in 1968.

Limestone slurry mixing with Moose Lake water at the Narrows dam to neutralize acid water. The limestone slurry is -325 mesh. Depending on requirements, from 3.5 to 9 tons per day of limestone is consumed.

Operation of Moose Lake Neutralization Plant

Due to the slight excess of limestone normally added and the large volume of the lower reaches of the lake, water discharging into Moose Creek is consistently neutral. This allows for safe and economical m[illegible] control of the neutralization plant. To insure minimum surveillance, it was decided to use limestone that was sufficiently coarse to prevent hangups in the storage bin even when wet, but sufficiently fine to be fed to the system using a conventional screw feeder.

In the neutralization plant, -½ + ¼-inch limestone chips are wet-ground to a fine powder, 90 per cent of which passes a 325-mesh screen, mixed with water and discharged at the rate of 200 gallons per minute over the Moose Lake Narrows dam weir to blend with and neutralize the acid water. The plant was designed and constructed by Falconbridge to operate unattended, with minimum supervision and maintenance.

TABLE II—Effects of Retention Time and Neutralization

Analysis Results ppm	Tailings Water at Tailings Dam	Moose Lake Outlet	
		Before Neutralization	After Neutralization
Dissolved Solids	987.	330.	390.
Suspended Solids	1.5	1.0	1.0
Sulphate Before Oxidation	555.	195.	206.
Sulphate After Oxidation	679.	194.	206.
Total Fe	6.	2.	0.6
Total Ni	0.6	0.3	0.3
Total Cu	0.5	0.1	0.1
pH	6.4	3.5	7.2
C.O.D.	46	less than 1	less than 1

FIGURE 3—Neutralization plant layout

Limestone, stockpiled outside the plant is loaded once weekly, under normal operating conditions, through the bucket elevator into the 50-ton bin. It is fed through the screw feeder at rates varying between 3.5 and 9 tons per day, manually adjusted, depending on the rate of water flow in the weir, directly into the ball mill. Water, added at a rate of 1 gal/min., serves to effect wet grinding at about 60 per cent solids in the mill. The grinding medium consists of 275 lbs. of 2.5-in. diam. and 700 lbs. of 1-in.-diam. steel balls. For the average grinding rate of 5.5 tons per day, about 15 lbs. of steel are consumed.

The annual operating expense of the plant averages $27,000, of which $15,000 is the cost of limestone and $2,000 the cost of power. Equipment repair and maintenance amounted to about $6,000 in 1968, but dropped to about $4,000 in 1969. The ball mill is alarm-coupled to a service station located at the Fecunis mill 1½ miles away to ensure continuous surveillance by maintenance personnel.

TABLE III—Equipment List for Moose Lake Neutralization Plant

	Cost
Bucket Elevator	$ 3,500

40-hp motor	1,400
3x3 SRL Limestone Slurry Discharge Pump & Motor	1,000
Wood-stave Tank	1,000
Mixing Turbine Agitator and Water Level Controller	2,000
Total Cost of Equipment	$ 31,300
TOTAL COST OF PLANT ERECTED	$100,000

Discussion

Two unsuccessful approaches to the elimination of acidity in Moose Lake are considered worthy of a brief description.

One initial concept of the problem was that excess alkalinity at the mill may, if sufficiently large, counter the acidity generated in the oxidation reaction. The polythionate-C.O.D. problem was recognized, but its

Onaping's Ron Rhude, pump operator, left, and Brian Potter, Technical Assistant, examine the 4'x6' DENVER Ball Mill, heart of the lime slurry production system.

The Strathcona Mill treating copper-nickel ore in the Onaping, Ontario, area. It is the tailing water from this new plant which is neutralized in the Moose Lake water treatment system

importance was not realized. Thus, a relatively simple solution appeared to be merely to add lime to the tailings disposal lines, utilizing equipment already available in the concentrator. An experiment of this nature was carried out and, although the pH of the decant water from the tailings pond was raised to 9.5, the oxygen demand and the free acid both increased substantially. The reason for this is that the mineral pyrrhotite becomes more reactive in an alkaline solution, resulting in a greater quantity of dissolved sulphur and the subsequent production of greater quantities of acid.

An attempt was also made to develop an intensive biological system that would produce a reduction in the C.O.D. in the same manner that a sewage system operates[12]. The bacteria *thiobacillus thioxidants*, which was identified in the tailings pond, was cultivated in the laboratory and introduced into samples of tailings pond decant solutions. The C.O.D. of these solutions was monitored for a two-month period and, although there was a reduction in the concentration of polythionates, it was insufficient to give any promise of being practically effective.

The water in Cranberry Lake, which receives the effluent from the Fecunis Lake tailings pond, has been monitored for a number of years and the results of 17 consecutive months are shown in Table IV. These results show that the combined chemical and biological processes which result in the oxidation of the polythionates are ineffective in November and December, presumably because of low water temperatures, inoperative under the ice cover from January through April, slow during the first two months of open water in the spring, while the water is warming up, and only truly effective during the months of July through October, during which period all or most of the C.O.D. is removed.

During the months of April, September and October, water samples from Cranberry Lake can indicate unrealistically low sulphate concentrations. These, however, are the months when precipitation in the Sudbury District is highest and the results are a reflection of the dilution which occurs.

200 gallons per minute of limestone slurry are mixed with water in the flume at the Moose Lake Narrows Dam. The System has been effective in raising the pH of water in the Moose Lake outlet from 3.5 before the neutralization to 7.2 after the lime slurry treatment.

The retention period in Cranberry Lake, which receives the water decanting from the Fecunis Lake tailings pond, has been estimated as six weeks. Analysis of water flowing out of this lake during the summer months reveals that complete oxidation of the sulphur compounds has taken place during this retention period. Lacking any other evidence, six weeks is considered to be the ageing time required under optimum conditions to effect complete polythionate oxidation.

There was some concern that the proximity of the discharge from Cranberry Lake to the Moose Lake Treatment System dam might permit unoxidized polythionates to escape during the winter months or early spring if unnatural flow patterns developed in Moose Lake. This has not occurred and, over two winters of operation, no sample taken at the dam has indicated any appreciable C.O.D.

To summarize, it would appear that in order to insure that neutralization will be effective, a retention period of approximately six weeks under open water and an active biological environment must be available

The new nickel-iron refinery of Falconbridge Nickel Mines Limited, at Falconbridge, Ontario. The main mill of Falconbridge Nickel Mines Limited is seen in the background.

Derek Ellot is pictured conducting tests on water sample taken from Moose Lake, to check on water treatment and circulation system. The Space-age instrument in the main analytical laboratories at Falconbridge during this test is an atomic absorption spectrophotometer.

from the time the effluents discharge from the tailings dam to the time the neutralizing limestone is added. In addition, in the spring eight weeks are required from the time the ice has vanished to the time the biological system of the lake becomes sufficiently active to oxidize the polythionates.

The operation of this system has been essentially trouble-free and its effectiveness has been entirely satisfactory. The biological life cycle in the lower part of Moose Lake below the neutralization plant has been restored. In fact, last summer minnows began showing up in the plant's process water system, indicating that the quality of water at the lower reaches of Moose Lake has been restored.

Finally, a few words on the cost of operation of the neutralization plant. The amount of limestone required to neutralize the 18.5-million-gallon average daily outflow from a pH of 3.5 was estimated using equation (6) at 4.5 tons. The cost to date, including the write-off of the plant's equipment, but excluding the cost of the dam, building, etc., is about 0.7 cent per 1,000 gallons of water treated—very reasonable considering that the acceptable cost of treating process water exceeds 10 cents in many parts of North America. Thus, work at Falconbridge has proved that effective acid neutralization for pollution control and improvement of process water quality can be carried out with a modest investment and low operating costs.

Acknowledgments

The writers wish to gratefully acknowledge the encouragement and advice given by W. L. W. Taylor, manager, Technical Services, and the useful criticism offered by J. E. Finlay, assistant general manager, Falconbridge Nickel Mines Limited, Sudbury, Ontario.

ROSSING URANIUM LTD.

ROSSING URANIUM LTD. treats 35,000-44,000 metric tpd ore to extract uranium by sulfuric acid leaching. 80,000 m^3/d tailings at pH 1.8 are pumped to a large impoundment area constructed of tailings material by upstream deposition of tailings pulp via spiggots. The tailings dam is built on relatively permeable material overlying a marble rock base. Seepage is collected for use as recycle solution. This is a form of passive water treatment. Compare the quality of the tailings effluent and recovered seepage.

EAGLE-PICHER INDUSTRIES, SHULLSBURG MINE, WISCONSIN

HOFFMAN (1984) described the impact on groundwater quality of the EAGLE-PICHER zinc mines near Shullsburg, Wisconsin, which closed in 1978 and 1979.

The mines were pumped dry during their working life; however, after closure they became flooded, and groundwater was affected to the extent that well water in the area is not suitable for use by humans or for livestock watering.

Closure of underground zinc-lead producing mines appears to have caused degradation of associated ground water resources. Changes in groundwater chemistry implied that acid mine drainage mechanisms were responsible for altering associated private water supplies in the area.

Groundwater quality in the Galena-Plattville dolomite aquifer experienced deterioration due to significant increases in dissolved sulfate (to 3500 mg/l). Other impacts were noted with dissolved iron (to 65 mg/l) and lesser quantities of zinc, lead, and arsenic. Field observations indicated that bacterially accelerated acid oxidation of FeS_2 with precipitation of $Fe(OH)_3$ produced micro-environments that were shielded from neutralization by the surrounding dolomite. Dissolution of relatively soluble iron, calcium, and magnesium sulfates on reflooding were probably responsible for the high values of sulfate. Where acid neutralization occurred, polythionate and thiosulfate salts may have yielded additional sources of sulfate.

The important aspect is that one would have expected dolomitic rock and soils to attenuate the formation of AMD and to avoid excessive levels of sulfate and metals. In this case, due to the high solubility of $MgSO_4$, however, the water quality turned out to be much, much worse than would have been expected at first, and natural attenuation of AMD could not be relied upon.

This is also a practical example of the phenomenon whereby even gypsum precipitation will be inhibited when magnesium is present. In some cases, solutions which, based on their Ca^{2+} and $SO_4^{=}$ levels, should be scaling are not when Mg^{2+} is also in solution.

GREENSIDE COLLIERY, WITBANK, TRANSVAAL

GREENSIDE COLLIERY is part of GOLD FIELDS OF SOUTH AFRICA LTD. and must treat a 220 m^3/h flow of acid mine drainage from the underground mine.

The flow of water into the mine has been reduced as much as possible, but there remains 220 m^3/h to treat. A plant was designed using crushed limestone in an innovative way. A commercial installation was to be installed by mid-1984.

Water was to flow upwards through a multi-compartment, deep trough filled with crushed limestone at minus 19 mm (0.75 inches). It has been found in laboratory tests that pH adjustment would be satisfactory after just six minutes contact time with limestone of this sizing, to comply with South African effluent pH limits of pH 5.5-9.5. Optimum time for

contact between water and the limestone was estimated at ten minutes, and there was not much further increase in the pH from 10-60 minutes contact time. Tests indicated that pH 6.3 could be achieved in 15 minutes and pH 8.5 after prolonged contact.

At regular intervals the activity of the limestone, as it becomes passivated by surface coating of $CaSO_4$, would be restored by vigorous agitation of the limestone in the troughs using an air sparge.

Reaction rate is faster with smaller limestone particles, but there was found to be a minimum practical size for the agitation attrition step without losing the bed.

During the air sparging cycle, the overflow was designed to be temporarily diverted to a lamella clarifier to clarify the neutralized water and settle a sludge.

Limestone could be supplied from a local quarry at a very attractive price compared with lime.

- The sole purpose of this treatment step was to modify pH as metal values meet the discharge limits. Composition of inflow and treated water based on laboratory tests were as follows:

	Untreated	Treated
pH	0.4	6.6
Ca Hardness as $CaCO_3$ ppm	496	553
Mg Hardness as $CaCO_3$ ppm	1340	1527
Total Hardness $CaCO_3$ ppm	1836	2080
Calcium as Ca	198	221
TDS	3500	3700
Suspended Solids	25	27

- In all tests, a fine sludge was formed during the neutralization process. This sludge required flocculation and settling for removal Lamella thickener tests indicated that a 3-4% solids sludge would be achieved which could be dried on "drying beds."

- Unless the process is operated in an upflow mode, the bed was found to "choke" with sludge.

- After treatment in the above way, the water would be suitable for discharge or for recycle to the operation as process water. Greenside Colliery planned to use the water in a coal preparation plant.

- The result of the commercial installation was failure, as indicated by David Blane's letter, due to blinding by ferrous salts.

The limestone neutralization facility was to be installed by:

Attention : Mr. Hans von Michealis

Dear Sir,

RE : LIMESTONE NEUTRALISATION PLANT

Your letter of the 15th October 1984 refers. Firstly my apology for the delay in responding, but we were delayed in the commissioning of the plant, and I wished to give you an accurate assessment of its capabilities.

However I have to report failure. On commissioning we found that the formation of ferrous salts soon coated and then slowly blinded the limestone, rendering the plant ineffective. Our various attempts to overcome this problem have not been successful, and the client is reverting to a lime-slurry neutralisation system.

I was extremely interested to hear of the three plants you have found operating in the USA, and would greatly appreciate any further information you could possible send me, such as location, owners, and any technical details you might have.

Thank you for the interest you have shown in our project.

Yours sincerely,
WATERCARE (S.A.) (PTY) LIMITED

MINE WATER RESEARCH

The Limestone Neutralization Process

by

E. A. Mihok,[1] Maurice Deul,[2] C. E. Chamberlain,[3] and J. G. Selmeczi[4]

ABSTRACT

A pilot plant for treating mine drainage by neutralization with limestone was designed, fabricated, and operated by the Bureau of Mines. The process consists of (1) producing a very fine (minus 400-mesh) limestone slurry, (2) mixing the slurry with the mine water, (3) aerating the resulting mixture to remove carbon dioxide and precipitate iron, and (4) separating the solids from the liquid by sedimentation.

A mine discharge of pH 2.8, containing 1,700 ppm total acidity, 36 ppm ferrous iron, and 360 ppm total iron, was treated at rates from 300 to 400 gpm. The treated water ultimately reached a pH of 7.4 and contained no detectable iron. The resulting sludge compacted to approximately one-third the volume of sludge from mine water neutralized with lime.

The advantages of the limestone process, compared with the conventional lime process are as follows: Widespread distribution and lower cost of run-of-mine, indigenous limestone; simplicity of plant design; reduced hazards and plant operating and maintenance costs accruing from the use of a less reactive chemical agent; higher solids concentration of the precipitated sludge; and no deleterious effect caused by accidental overtreatment.

While total process costs could not be determined, it is conservatively estimated that the cost of treating mine water by the limestone process is one-third to one-half the cost of the lime process, depending on the characteristics of the water to be treated and the availability and quality of limestone used.

INTRODUCTION

In 1966, the Bureau of Mines, as a special adjunct to its comprehensive research program on the chemistry of mine water and at the request of a group of coal mine operators, undertook a short-term project to develop an effective treatment process for mine water. The work was primarily concerned with neutralization and iron oxidation, although sludge settling characteristics and dewatering techniques also were studied.

The emphasis on the use of limestone as a neutralizing agent was due mainly to its low cost and easy availability. In 1967, a report was published which showed that coarse limestone was potentially useful for treating mine waters.[5] Additional papers by Mihok and Chamberlain,[6] and by Kim[7] provided information on limestone neutralization and iron oxidation. F. P. Calhoun[8] gave performance and cost data on limestone treatment of a Rochester and Pittsburgh Coal Co. mine effluent.

The original concept in the use of coarse limestone was that the sustained reactivity achieved by vigorous cascading agitation in a rotating vessel (1) provided abrasion to eliminate the coating of limestone particles with precipitated solids, (2) continuously renewed the reactive surface, and (3) removed the CO_2 from solution. A large aeration surface facilitated oxidation of ferrous iron. Adequate treatment for water containing high acidity and moderate amounts of soluble iron was limited to flows of less than 100 gpm. This concept was expanded and improved upon during the pilot plant tests reported here.

ACKNOWLEDGMENTS

The successful prosecution of this research was made possible through the mutual cooperation of the management of the Vesta-Shannopin Division of Jones & Laughlin Steel Corp., who provided unstinting assistance with manpower, material, counsel, and a treatment site where the research could be conducted; and the Research and Development Division of Dravo Corp. which, through a cooperative agreement, provided financial assistance.

MINE WATER TREATED

Preliminary tests conducted with a tube mill reactor were made with synthetic mine water solutions at the Bureau of Mines.[9] To determine the performance of the limestone system with a natural mine water, the tube mill and auxiliary equipment were installed at the Jones & Laughlin Steel Corp. Shannopin No. 1 air shaft borehole treatment site near Bobtown, Greene County, Pa.

An existing 3-million-gallon-capacity holding lagoon was used to level off the variable composition of the water pumped from the mine, and to obtain some reduction in ferrous iron by natural oxidation. This provided a mine water of fairly uniform composition for tests. Typical analyses of the mine water treated are shown in table 1.

TEST PROCEDURE

Limestone Process

The limestone pilot plant consisted of a 3-foot-diameter by 24-foot-long tube mill driven by a 15-horsepower variable-speed motor; a slurry discharge trough and sump; a 60-foot-long, 2-foot-diameter, semicircular mine water feed and mixing trough; and a 60,000-gallon-capacity, earthen, limestone-riprap-lined aeration pond equipped with a surface aerator and air blower sparging system. Later, a 35,000-gallon-capacity sedimentation pond was constructed between the aeration pond and the existing large settling basin. Figure 1 is a flowsheet of the limestone process. The major components of the treatment pilot plant are illustrated in figures 2 through 5.

Mine water from the holding pond was fed by gravity through plastic pipe simultaneously to the tube mill and mine water feed trough. A 1/4-inch screen

[9]Work cited in footnote 6.

with a 7-inch circular opening was mounted near the feed end of the mill. A similar screen, but without an opening, was located at the discharge end of the mill. A hinged watertight end plate with a 10-inch circular opening, contained the water within the tube mill and provided a hydrostatic head for flow. A 6-inch-diameter plastic pipe carried water into the tube mill, and limestone was added to the mill through an opening in the top of the pipe. Four equally spaced 1/4- by 2-inch angle irons, spirally mounted inside the mill, served as lifters and prevented sliding of the stone. The feed end of the tube mill was raised about 4 inches to permit higher limestone loads.

Limestone Used

The limestones for the tests were obtained locally from quarries at Smithfield, Pa., and Morgantown, W. Va., as standard commercial products. Two low-grade argillaceous limestones, double-screened 3- by 1-inch, and 1-1/2-inch by 0 crusher run sizes, were used. During the testing, a labor strike at one quarry made it necessary to find another source of limestone. The analysis of the limestones is shown in table 2. Both limestones were dark gray and contained undetermined amounts of organic matter; a fetid odor emanated from the tube mill while in operation.

Grinding Tests

The amount of fine limestone generated in the tube mill at 25 rpm was determined in a series of tests with various limestone loads and water throughputs. Results of these tests showed that very fine limestone is generated; over 90 percent passed through 400 mesh. With waterflows of 60 gpm or more through the tube mill containing approximately 7,000 pounds of 1/4- by 3-inch limestone, only 1.6 pounds per minute of fine limestone was produced. With comparable limestone loads at about 10 gpm of water, up to 6 pounds per minute of fine limestone was produced. More than 8 pounds per minute of fine limestone was generated with higher limestone loading (9,000 pounds). Figure 6 shows particle size distributions of the fine limestone produced as determined with a recording microsedimentation balance. A sample of the slurry produced in a 6-hour test contained particles 98.6 percent of which were finer than 400 mesh. The median size of the particles was about 8 microns. A photomicrograph of the limestone slurry (fig. 7) shows a high percentage of

FIGURE 6. - Particle Size Distribution Curves of Limestone Slurry Produced in the Tube Mill.

extremely fine particles in the 1- to 5-micron range. The generation of fine limestone in the tube mill is shown in table 3.

FIGURE 8. - Precipitated Neutralization Products From Mixing Trough. Note small gypsum crystal and floc formation.

TEST RESULTS

If the mine water to be treated must flow through the tube mill, its maximum capacity is about 100 gpm for this particular mine water. By using the tube mill solely as a device to generate a fine limestone slurry, which is subsequently added to the mine water, over 450 gpm could be treated. This rate could not be sustained owing to inadequate power supply. A flow of from 300 to 325 gpm was treated continuously during a 6-hour run.

At the start of the test summarized in tables 4 and 5, the tube mill contained approximately 7,500 pounds of smoothly rounded limestone ranging in size from 1/4 to 3 inches. Three- by 1-inch limestone, assaying 72.0 percent $CaCO_3$ and 5.6 percent $MgCO_3$, was added continuously to the reactor at a rate approximating the consumption rate for the first 2 hours; thereafter, 1-1/2-inch by 0 limestone, assaying 82.0 percent $CaCO_3$ and 2.4 percent $MgCO_3$, was added at a higher feed rate. The mill contained approximately 9,000 pounds of limestone at the end of the test. This resulted in the production of 2.2 pounds per minute more $CaCO_3$ than needed to neutralize the total acidity in the water at the 300- to 325-gpm flow rate. The amount of fine limestone produced was capable of treating up to 480 gpm, which is more than the average discharge from the borehole. If a pure limestone were used, as much as 600 gpm of this water could be treated.

[1]Represents about 80 percent of total solids produced; the other 20 percent is inert material.

Approximately 5 seconds elapses between the time the limestone slurry from the tube mill mixes with the mine water and the time it discharges into the aeration pond (fig. 8). Precipitates are already forming during this brief interval. The pH of samples taken from the end of the mixing trough is greater than 5.0. The suppressed pH is due almost entirely to dissolved carbon dioxide. This phenomenon is discussed more fully later in the report. The surface aeration and limited air sparging applied continuously in the aeration pond was adequate for these tests, but efficient air sparging is essential to achieve the high pH for removal of high concentrations of ferrous iron. Figure 9 shows the dispersed precipitated gypsum and iron hydroxide flocs in the effluent from the aeration pond.

Neutralization Rate

Acid neutralization batch tests in the laboratory, with a fine limestone slurry, indicated that air sparging removes CO_2 from the solution at a significantly higher rate than stirring (fig. 10).

FIGURE 9. - Gypsum Crystals and Precipitated Floc in Effluent From Aeration Pond.

Studies were conducted in the laboratory using mine water with a limestone slurry containing 98 percent minus 400-mesh particles. A 12- and a 60-percent excess of limestone alkalinity were used. Comparable tests with slaked quicklime slurries and mine water were conducted. The limestone- and lime-neutralization rates are shown in figure 11. Air sparging was used during the limestone tests to

FIGURE 10. - Effect of Carbon Dioxide Removal on pH in Limestone Neutralization of Acid Solutions. CO_2 concentrations based on carbon dioxide-carbonate equilibrium data in aqueous solution (25° C). (Kern, David M. The Hydration of Carbon Dioxide. J. Chem. Ed., v. 37, No. 1, January 1960, p. 17.)

FIGURE 11. - Batch Tests of Neutralization of Acid Mine Water With Lime and Limestone Slurries.

expedite carbon dioxide removal. These tests are not as efficient as pilot tests, in which the more reactive particles are supplied continuously, but they do illustrate the importance of air sparging to remove dissolved carbon dioxide to achieve a high pH rapidly.

Settling and Compaction of Precipitated Solids

Settling and compaction tests were made on lime- and limestone-neutralized mine waters. The water was treated to the same end conditions; that is, to a

FIGURE 12. - Heights of Precipitated Sludge From Lime- and Limestone-Neutralized Water After Settling for 1, 5, and 43 Days as Percent of Total Volume of Treated Water.

pH of 6.9 and with no detectable iron remaining in solution. Glass cylinders, 2-5/16 inches in inside diameter and 48 inches long, with a capacity of 4.9 liters were used. Lime- and limestone-neutralized waters were put in separate cylinders and allowed to settle. The resulting data are shown in table 6 and illustrated in figure 12. After 1 day, the volume of sludge from limestone neutralization was less than one-fourth the volume produced by lime neutralization. After 43 days, the sludge volume from the limestone process was less than one-third the volume from the lime process. This difference in sludge volumes is significant for treatment plant design and in reducing the volume of sludge to be disposed.

An attempt was made to determine the influence of depth on sludge compaction. equal volumes of sludge were prepared for the test. To produce 4.9 liters of settled sludge after 1 day of settling, 27 liters of lime-neutralized mine water was required compared with 128 liters of limestone-neutralized mine water. The supernate was decanted, and the remaining sludge was allowed to settle in glass cylinders for 42 more days. These data are given in table 7 and illustrated in figure 13 for easy comparison with table 6 and figure 12. This simple scale-up is inadequate to establish absolute sludge compaction properties; however, the data do indicate that there is no compaction for the lime-neutralized sludge and that the limestone-neutralized sludge compacts slightly.

TABLE 6. - Height of settled solids of lime- and limestone-treated waters

The effect of solids concentration on hindered settling in a primary sedimentation pond and the potential for gypsum crystal growth with time are two important factors that could not be studied within the scope of this project.

A high-solids concentration of limestone-neutralized sludge rapidly produces a clear supernate. A low-solids concentration, which permits free settling, requires a longer time for water clarification. This is a well-known phenomenon[10] that should be considered in the design of thickeners, clarifiers, and settling ponds, especially where land area is a prime consideration.

Earlier experiments with limestone neutralization indicated that after agitation, limestone-neutralized solids tended to settle more rapidly as they aged. A possible explanation for this effect is the continual growth of gypsum crystals already present in the sludge. Such growth would affect

[10]Coe, H. S., and G. H. Clevenger. Methods for Determining the Capacities of of Slime Settling Tanks. Trans. AIME, v. 55, 1917, pp. 356-384.

FIGURE 13. - Heights of Sludges Produced From Lime Neutralization of 27 Liters of Acid Mine Water and From Limestone Neutralization of 128 Liters of Acid Mine Water as Percent of Total Volume After 1 Day's Settling.

materially the settling characteristics of the sludge and may be an important factor in liquids-solids separation.

ECONOMICS OF LIMESTONE TREATMENT

The limestone process has inherent advantages over the conventional lime process; namely, lower cost, widely available raw material, simplicity in design and operation, and much smaller volume of precipitated solids. The limestones used in these tests were low grade, argillaceous limestones costing about $3 per ton delivered at the site in small lots. A standard lime product would have cost about $20 per ton.

To treat 1 million gallons per day of mine water, containing 2,000 ppm total acidity as $CaCO_3$, would require 16.6 tons per day of limestone (assuming

FIGURE 14. - Gypsum Crystals and Precipitated Floc From the Sedimentation Basin.

only 50 percent utilization based on inerts and excess $CaCO_3$) costing $50 per day, compared with 6.2 tons of hydrated lime (assuming 100-percent efficiency) costing about $120 per day. The savings in cost of raw material alone would amount to at least $25,000 per year.

Fine reactive limestone in slurry form can be generated in a simple tube mill and operated with a minimum of maintenance and control. Power requirements for generation of fine limestone in the tube mill are comparable to those of commercial grinding devices. With a power rate of 1.5 cents per kilowatt-hour, the cost of generating 1 ton of fine limestone is approximately 67 cents.[11]

Bulk handling techniques for coarse stone and slurry are available to permit low-cost, efficient operation. Because over-neutralization to a pH greater than 8.4 is impossible, expensive precision controls are not required; standard aeration equipment is adequate.

The rapid settling and higher compaction characteristics of limestone sludges, compared with lime sludges, indicate that settling basin requirements would be reduced considerably. Figure 14 shows the coarse mat of gypsum crystals and flocculated solids from the sedimentation pond. Since solids waste disposal is as much a problem as neutralizing acidity and removing soluble iron, a minimum threefold reduction in sludge volume is a distinct advantage.

CONCLUSIONS AND RECOMMENDATIONS

Limestone neutralization is an effective and low-cost method for treating ferruginous acid waters. This has been demonstrated at a mine discharge site where 300 to 400 gpm of mine water at a pH of 2.8 and containing 36 ppm ferrous iron (Fe^{++}), 360 ppm total iron (Fe), and 1,700 ppm total acidity--determined by the hot phenolphthalein method--was treated to yield a primary effluent containing less than 7 ppm iron, no acidity, and a pH of nearly 7. Overnight settling in a small sedimentation pond produced an alkaline final effluent having a pH of 7.4 containing no detectable iron.

[11] Perry, R. H., C. H. Chilton, and S. D. Kirkpatrick. Chemical Engineers Handbook, 4th ed., McGraw-Hill Book Co., Inc., New York, 1963, sec. 8, p. 47.

The limestone-treatment process, compared with the conventional lime-treatment process, has the following advantages: (1) Widespread distribution and lower cost of run-of-mine, indigenous limestone, (2) simplicity of plant design, (3) reduced hazards and plant operating and maintenance costs accruing from the use of a less reactive chemical agent, (4) higher solids concentration of the precipitated sludge, (5) no deleterious effect caused by accidental overtreatment, and (6) total treatment cost estimated to be one-half to two-thirds lower.

This process has general application for treating mine waters of the wide range of acidity and iron normally encountered, provided enough fine reactive limestone is available in slurry form to neutralize the acidity and sufficient aeration is provided to remove the dissolved carbon dioxide to create the high pH environment required for rapid iron oxidation and precipitation.

Based on the results of these tests it is recommended that, where pollution abatement measures cannot eliminate acid mine drainage, the limestone neutralization process be used to treat the persisting mine water effluent to produce an acceptable discharge. It is further recommended that, to effect maximum economies in treatment costs and in land conservation, consideration be given to use of the limestone neutralization process wherever other treatment processes are now in use or are contemplated. Milling of limestone to micron sizes, techniques of aeration, and sludge handling are aspects of the limestone neutralization process that can be optimized, and it is recommended that engineering studies be conducted in these areas.

INT.-BU.OF MINES,PGH.,PA. 12926

TENNESSEE CLAY DEPOSITS - AMD

Overburden from some ballclay deposits in Tennessee yields acid mine drainage with a pH of around 4, too low to be discharged. The pH is adjusted very simply by allowing the effluent to seep through a pile of limestone. This system works adequately and is completely passive. More information could be requested from:

AMOCO METALS CO.

Mark Passarini

ALKALINE MINE DRAINAGE

Occasionally mine drainage may have a high pH and, on standing, an algal bloom develops which increases the pH to 8.5-9.5, which is also too high to discharge. The algae consume CO_2 in the water which results in part of the increase in pH which must be reduced to pH 6-9 for discharge in terms of most NPDES permits. This phenomenon occurs usually in summer, for example in stormwater storage impoundments into which nutrients have been added, e.g., by addition of water reclaimed from secondary sewage treatment or settling ponds used to settle fine coal.

One company brings the pH to within effluent limits by acidifying with CO_2. An alternative way would be to add a small dose of sulfuric acid, but this involves handling, transporting, and storing a hazardous chemical.

BUREAU OF MINES 1967

MINE WATER RESEARCH

Neutralization

by

Maurice Deul[1] and E. A. Mihok[2]

ABSTRACT

A special short-term research project was initiated to develop plant design parameters for treating mine waters to yield an effluent acceptable for discharge into streams and a sludge amenable to effective and economic disposal.

Neutralization was investigated to provide simple and direct treatment of ferruginous acid waters using lime, coarse limestone, and limestone followed by lime. Limestone treatment was accomplished using a small cement mixer as a simple reactor to provide abrasive agitation of limestone and mine water. Results from tests with nine mine waters encompassing a wide range of iron and acid concentrations showed that coarse limestone, one of the cheapest neutralizing agents known, is potentially useful for treating mine water discharges. However, process variables must be defined more completely before the practical applications and limitations of the process can be fully established.

In all the tests a pH of >7.2 was obtained ultimately with limestone. Reaction time to reduce the iron content below 7 ppm in the water was dependent on the original ferrous iron concentration. For waters with high ferrous iron content, treatment with limestone followed by lime rapidly produced an acceptable treated water. Sludges with good settling and handling characteristics resulted when limestone was used for neutralization either alone or with subsequent treatment.

Reaction rates are expressed graphically as pH change and iron depletion curves; characteristic solids settling curves are shown. The temperature dependency of ferrous iron oxidation was verified.

CONCLUSIONS AND RECOMMENDATIONS

Coarse limestone in a dynamic state with mine water and air has been demonstrated to provide sufficient sustained action to neutralize acid and to remove iron. For mine waters containing low to moderate concentrations of iron, the treated water had a pH of 7 to 8 and an iron concentration of less than 7 ppm; the precipitated solids compacted well. Mine waters high in ferrous iron required long reaction times (>15 min) with coarse limestone, and the treatment had to be supplemented with lime in a second stage to produce acceptable waters in a short reaction time. Nine mine waters of widely ranging acid and iron concentrations were treated by one or more of these methods for comparison with lime neutralization. These exploratory investigations show that coarse limestone, one of the cheapest neutralizing agents known, is potentially useful for treating mine water discharges.

It is recommended that investigations of neutralization processes should continue to (1) study the effect of contributing factors to the overall reaction such as size distribution and composition of limestone, residence time, temperature, degree of agitation and abrasion, and air-liquid-solid interfacial area; (2) design an efficient reactor to treat large volumes; and (3) develop plant design criteria for neutralization of acid mine waters.

INTRODUCTION

The Bureau of Mines, as a special adjunct to its comprehensive research program on the chemistry of mine waters, recently undertook a short-term project to define quickly and clearly the investigative effort that would be required to develop practical plant-design parameters for treating acid mine water. This project was initiated by the Bureau's Director, at the request of a group of coal mine operators, with the long-range goal of yielding an effluent acceptable for discharge into streams and a sludge amenable to effective and economic disposal.

A research program was outlined and implemented, encompassing an extensive field of investigation including neutralization, oxidation, settling characteristics, and sludge dewatering techniques. It was generally agreed that water treatment testing should consist of neutralization with lime, with limestone, and with limestone followed by lime. The emphasis on the use of limestone as a neutralization agent was due mainly to its low cost and easy availability.

ACKNOWLEDGMENTS

The cooperation of many representatives of the coal mining industry is gratefully acknowledged. These included Rochester & Pittsburgh Coal Company; Pittsburgh Coal Company, Division of Consolidation Coal Company; Bethlehem Steel Company; Powell Coal Company; and Jones & Laughlin Steel Corporation. Without their assistance and personal guidance in site selection, their making available temporary field laboratory space, and free access to their records of water analyses, progress of the work would have been much slower. The free exchange of information is exemplified by the disclosure by Rochester &

Pittsburgh Coal Company officials that they had been investigating a promising limestone neutralization process.

We are grateful for their demonstrated concern for maintenance of safe working conditions in crowded and potentially hazardous locations.

We also acknowledge the efforts of C. E. Chamberlain, chemist, and K. D. Curley and Fred Pichi, technicians, for their high efficiency throughout a difficult and arduous field program.

WATERS TESTED

A reconnaissance survey and sampling of mine waters representing a wide range of composition were conducted on sites of the cooperating coal mining companies. Nine mine water discharges were selected. Typical analyses of these waters are presented in table 1.

TABLE 1. - Analysis of mine waters collected during reconnaissance

Mine water	A-1	A-2	B-1	B-2	B-3	C-1	D-1	E-1	E-2

[1]End point = pH 8.20 at 60° C.
[2]Not determined.

The composition of any mine water discharge is variable and subject to almost daily fluctuation. The waters used in the field tests were taken 1 to 2 months after the reconnaissance sampling. The composition of the mine waters actually tested and the test results are given in the section describing the test results.

TEST PROGRAM

Procedure

The characteristics of mine water change with time; consequently, it was necessary to conduct experimental work at the point of discharge. The field equipment consisted of laboratory analysis facilities and neutralization, settling, and filtration equipment. Samples of mine water were taken from the discharge for analysis and neutralization. The reaction was monitored for pH and for ferrous iron concentrations. In most cases, the initial test was run

beyond the point of complete iron removal to obtain a pH trend in the neutralization process. When that point was determined, additional batches of neutralized water were made to provide sufficient volume for settling and filtration tests. Samples for detailed analysis at the Bureau of Mines laboratories were withdrawn at various stages of treatment. This procedure was substantially the same for all water treated.

Reactor

A modified cement mixer, 1/4-cubic-yard capacity, was used as a reactor (fig. 1). Except for continuous tests, all neutralization tests were conducted on a batch basis, keeping the reactor conditions constant. Rather than design a reactor in the short time allotted this project, it was decided that a cement mixer could impart the necessary interaction between mine water, limestone, and air. The mixer was driven by a gasoline engine at constant speed of 22 rpm. The mixer was held at a set angle of tilt about 20° from the horizontal for all tests to insure containment of the limestone and prevent loss of water by overflow and splashing. The inside surface of the mixer was coated with an inert epoxy resin to prevent contamination of the waters by extraneous iron that might be dissolved by the acid water.

Neutralizing Agents

The neutralizing agents used for the tests were high-calcium, double-screened (1- by 1/2-inch and 1/2- by 1/4-inch) limestones and commercial hydrated lime. The analysis of the reagents is shown in table 2. The limestones were obtained locally from lime and stone companies as standard commercial products.

Iron	.29	.06		

[1]Not determined.

Analytical Methods

Methods of analysis used in the field are as follows:

1. pH. Determined by electrometric measurement by means of the glass electrode.

2. Acidity. Sample was oxidized and boiled to hydrolyze all iron salts and remove CO_2, then titrated with standard sodium hydroxide to an electrometric pH of 8.2 at 60° C.

FIGURE 1. - Photograph of Reactor.

3. Iron, ferrous. Sulfuric acid-phosphoric acid mixture and sodium salt of diphenylamine sulfonate indicator were added to the sample and titrated with standard potassium dichromate.

4. Iron, total. Sample was oxidized with bromine water, iron precipitated with ammonium hydroxide, filtered and redissolved with hydrochloric acid, reduced with stannous chloride, and titrated with standard potassium dichromate.

Other determinations were made in the laboratory as follows:

1. Carbon dioxide. Evolved by acid and absorbed in ascarite.

2. Sulfate. Precipitated as barium sulfate and weighed as such.

3. Calcium. Precipitated as calcium oxalate, ignited, and weighed as calcium oxide.

4. Magnesium. Precipitated as magnesium ammonium phosphate, ignited, and weighed as magnesium pyrophosphate.

5. Silica. Hydrochloric acid insoluble material was ignited and weighed; then evaporated with hydrofluoric acid to expel SiO_2. Difference in weight is SiO_2.

6. Water. Sample air dried at 85° F, then dried to constant weight at 105° C.

7. Solids, weight-percent. Net weight of sample obtained by weighing sample plus bottle, and subtracting weight of bottle. Filtered by gravity on weighed filter paper. Paper and contents dried at 105° C to constant weight.

8. Eh (oxidation potential). Electrometric measurement of oxidation potential by means of an electrode pair consisting of an inert (platinum) electrode and a reference (calomel) electrode.

Limestone Neutralization

The literature and laboratory tests on the use of limestone--coarse, powdered, and granular--as an acid neutralizing agent indicate that the terminal pH is usually in the range of 6.0 to 6.5. This pH, however, is not maintained on a continuing basis. The limestone reactivity steadily decreases; this is due in part to the deposition of reaction solids on the surface of limestone particles. Failure to remove carbon dioxide from the solution, resulting in the formation of carbonic acid, also inhibits the neutralizing action.

Exploratory tests in the laboratory using acid mine water with coarse (1- by 1/2-inch) limestone in a small cement mixer, which can be construed to be a tilted revolving chamber with baffles and lifter plates, resulted in a terminal pH above 8. The inordinately high alkalinity obtained gave immediate impetus to reinvestigate this reaction. The present explanation is that this

high pH is achieved by vigorous cascading agitation to provide (1) abrasion to eliminate coating of limestone particles with precipitated solids and continual renewal of reactive surface; (2) large aeration surface for oxidation of ferrous iron; and (3) removal of CO_2 from the solution.

Prior efforts to utilize limestone[3] as an alkaline agent were concerned with stoichiometric proportions or a small excess of limestone. Theoretically, smaller particles should contribute to greater activity. However, this is not the basis to maintain sustained high activity. A great excess of limestone is needed to provide a constantly renewed reactive surface. For most of the batch neutralization tests, the ratio was approximately 1 part water to 2 parts limestone, or 10 gal (83 lb) of water to 150 lb of limestone.

Lime Neutralization

Most industrial acid waste liquors are neutralized with lime. The lime used in the form of a quicklime, or hydrate, usually provides a cheap source of alkalinity. The reactivity of commercial lime is great enough to neutralize economically the acid and precipitate the high iron concentrations normally encountered in industrial waste liquors.[4] Since acid mine drainage, at worst, contains only a fraction of the acid and iron found in industrial acid waste liquors, the use of lime supplies a ready solution. The disadvantages in the use of lime as a treatment of mine waters are (1) the high cost of alkalinity and (2) that the precipitated solids occupy large volumes which must be disposed of with difficulty. The technology of lime treatment of acid wastes is highly advanced so that estimates of treatment costs can be obtained readily.

Limestone-Lime Neutralization

Another method of treating mine waters was investigated using primary treatment with limestone followed by secondary lime treatment. In most cases, the mine water was allowed to mix with the coarse limestone in the reactor for at least 1 min and then the lime was added in small increments until the pH of the solution reached 8 to 9.

Using limestone, long reaction periods were needed to treat mine waters high in ferrous iron. With lime, the same waters were rapidly neutralized, but larger amounts of reagent were required to precipitate all the iron. Therefore, a dual treatment using the two alkaline agents would produce an effect combining the best of both reactions.

[4]Hoak, Richard D., Clifford J. Lewis, Charles J. Sindlinger, and Bernice Klein. Lime Treatment of Waste Pickle Liquor. Ind. and Eng. Chem., v. 39, No. 2, 1947, pp. 131-135.

Continuous Limestone Neutralization

The limestone reactor was converted from batch neutralization to continuous operation. A raw water feed line was introduced into the reactor with the discharge outlet submerged in the coarse limestone. A discharge well was provided near the opening of the reactor for insertion of pH electrodes to continuously monitor the treated water discharge. Settling containers also were provided to collect concentrated solids and clarified effluent.

Piping difficulties imposed limitations on the raw feed supply. As a result, a flow rate of only 1 to 1-1/4 gpm was obtained. The first test was conducted with 150 lb of 1- by 1/2-inch limestone. The continuous operation was conducted for about 4-1/2 hours on the first day and for about 5-1/2 hours on the following day. Approximately 700 gal of raw water, pH 5.8 and ferrous iron content of 70 ppm, at a temperature of 12° to 13° C was treated. The equilibrium pH varied from 7.80 to 7.55. The ferrous iron concentration of the reactor discharge in the settling basin and the clarified effluent was determined at intervals throughout the test. Ferrous iron concentration in the treated water did not exceed 3 ppm.

The second test was conducted with 150 lb of 1/2- by 1/4-inch limestone at an initial raw water feed rate of 2.5 gpm, with pH of 5.6 and ferrous iron content of 90 ppm. A pH of 7.15 was obtained in the reactor and 7.35 in the settling basin. An additional 117 lb was added to the reactor. The pH rose slightly to 7.40, but considerable ferrous iron, about 50 ppm, was still present. The test was run for approximately 30 min. The temperature of the raw water in this test was 6° C (43° F).

The third test consisted of 300 lb of 1/2- by 1/4-inch limestone with a raw water feed rate of 2-3/4 gpm. After 30 min of operation, the pH steadied at 7.6. The ferrous iron content in the treated water was 22 to 28 ppm. The raw water feed was reduced to 2 gpm with a resulting pH of 7.8, but the iron content remained at 22 ppm. The temperature of this water was 6° C (43° F).

TEST RESULTS

pH Increase With Limestone Treatment

Figures 2 through 7 show the change in pH with time as the reaction progressed for all waters tested. The points on the curve indicate the time a sample of the water was withdrawn from the reactor and the pH determined electrometrically. The total reaction time was arbitrarily set at 20 min, with several tests prolonged beyond that.

Ferrous Iron Depletion With Limestone Treatment

Figure 8 shows the concentrations of dissolved ferrous iron (Fe^{++}) as the reaction progressed. The ferrous iron determination was made from the same sample that was withdrawn for pH measurement. Relatively few ferrous iron determinations were obtained. The ferrous iron concentration is dependent on

reaction time, but the determination itself is time consuming; therefore, reactor samples could not be saved for later analysis.

FIGURE 9. - Ferrous Iron Depletion With Limestone-Lime Mixed Treatment.

Ferrous Iron Depletion With Limestone-Lime Treatment

Figure 9 shows the ferrous iron depletion trend of several mine waters high in ferrous iron with a primary limestone treatment of 1 to 5 min, and with indicated amounts of hydrated lime added and mixed for the remaining time.

Sludge Settling Rates and Sludge Volumes

As soon as the neutralization process was completed, portions of the treated water were placed in 1-liter graduated cylinders for settling rate and sludge volume determinations. The results of these tests are shown in figures 10 through 18. Well-defined interfaces between settled solids and supernate were observed where there were high solids concentrations; dilute solids concentrations, especially those formed with lime, showed poorly defined interfaces in the early stages of settling.

These settling rate curves show that wherever limestone is used for neutralization treatment, either alone or with lime, the settling rates and volumes of compacted solids indicate more favorable conditions for solids-liquid separation than when lime alone is used.

It is obvious that the more rapid settling rates and high degree of compaction for limestone-treated water are due, in part, to the excess limestone abraded during the mixing action. This, of course, can be minimized but it is expected that the favorable influence of limestone on settling and

compaction characteristics will remain. The discussion of this effect will be deferred to a later report.

Summary of Batch Test Results

The analyses of the waters treated in the field and the results of all the batch neutralization tests are summarized in table 3. Also included are the volumes and weights of settled solids from the batch tests.

Continuous Treatment With Limestone and Ferrous Iron Depletion

Continuous limestone neutralization tests were conducted on the E-2 mine water using 1/2- by 1-inch and 1/4- by 1/2-inch limestones.

With low flow rates of about 1 gpm, the reactor operated satisfactorily; however, with higher flow rates, an effluent quality meeting minimum standards could not be attained. Thus, it appears that the reactor, as used for batch neutralization, was operating efficiently. The reactor functions as both a neutralizer and oxidizer; consequently, it was not possible to separate the reactions for rate studies of each separate process. Continuous neutralization could not be studied effectively at the flow rates used and under variable temperature conditions.

[4]10 gal of mine water added to 250 lb limestone (1- by 1/2-inch) in reactor at 22 rpm.

DISCUSSION

As mentioned in the Introduction, the use of limestone as a neutralizing agent in the treatment of mine water promises several important advantages. Lime is the most commonly used acid neutralizing agent and iron precipitant; consequently, the technology of lime neutralization is highly developed in water treatment and neutralization of pickle liquor from steel processing plants. Although there have been many attempts at using limestone for pickle liquor neutralization, none have been successful. Results of experiments described in this report indicate that the benefits to be derived from the use of limestone are greater than merely from the use of a cheaper reagent.

Mine waters have a much lower iron and acid sulfate concentration than pickle liquor, but the volume of water that may require treatment is many times greater and it must be recognized that, despite the general similarities, the differences are large.

Lime neutralization of acid mine waters yields a highly flocculent iron hydrate precipitate which does not compact well. In contrast, limestone neutralized mine waters do not yield a hydrophilic floc; the precipitated material is crystalline gypsum with coprecipitated iron oxide. A complete study of these contrasting reactions is being conducted as part of the continuing long range research program of the Bureau on the chemistry of mine waters.

The use of coarse limestone, with abrasive agitation, to provide a large surface of air-water-limestone interfaces appears to be the key to making limestone neutralization work. Fixed bed, coarse limestone and finely pulverized limestone reactions have failed in the past because surface coatings of neutralization products have hindered further reaction. Only in a dynamic system are reactive surfaces continuously renewed.

The oxidation of ferrous iron is highly temperature dependent.[5] This was demonstrated in limestone neutralization tests where a temperature drop of 5° C resulted in high ferrous iron concentration remaining in treated waters at a pH of about 7.5, in contrast with ferrous iron concentration less than 7 ppm achieved at pH 7.5 at 11° C.

For very high ferrous iron concentrations, the reaction time with limestone alone may be excessive. Yet with lime alone, the precipitated sludge would be extremely difficult to concentrate to a high solids concentration. The best effects of both reactions can be achieved by first neutralizing with limestone to a pH near 7, and using lime to complete the precipitation of the remaining iron. This is especially significant because the rate of lime neutralization of highly ferruginous acid waters is not well established. This too is being investigated as part of our long-range program.

WATERWHEEL LIMESTONE TUMBLER

A semi-passive limestone neutralization system for AMD treatment has been developed by the Pennsylvania Bureau of Abandoned Mine Reclamation. Their system places large limestone crushed rock into a cage on a shaft which is connected to a waterwheel. AMD is discharged so that it powers the waterwheel to turn the cage so that the limestone particles are constantly abraded. The water then flows over the limestone in the cage and into a settling pond. This system was not inspected, but it was confirmed that a large demonstration unit was installed to treat acid mine drainage at the Quakake Tunnel southwest of Wilkes-Barre, Pennsylvania. The major advantages of using crushed limestone rather than lime for AMD treatment are listed as follows:

- Low reagent cost (about one sixth the cost of lime).
- Low sludge volume and dense, easily dewatered sludge.
- The impossibility of overtreatment reduces process control costs.
- Safer reagent handling with minimal storage problems.
- Potentially simpler process design with reduced capital and operating and maintenance costs.

On the basis of this demonstration plant, it is believed that a full-scale demonstration plant will be installed at the headwaters of Little Tobie Creek in Elk County, Pennsylvania, again funded by the state.

A description of the large Quakake Tunnel Demonstration Project-Limestone Neutralization of Acid Mine Drainage in Carbon County, Pennsylvania, is described by a report for the Pennsylvania Dept. of Environmental Resources, prepared by:

GEO-TECHNICAL SERVICES, INC.
Consulting Engineers and Geologists
Harrisburg, PA

Additional information on the Quakake Tunnel Mine Drainage Pollution Abatement Study is contained in a detailed report for the Pennsylvania Dept. of Environmental Resources and from their office that managed the program:

ACID MINE DRAINAGE: CONTROL AND ABATEMENT RESEARCH

By Ann G. Kim,[1] Bernice S. Heisey,[2] Robert L. P. Kleinmann,[3] and Maurice Deul[4]

ABSTRACT

Acid drainage from underground coal mines and coal refuse piles is one of the most persistent industrial pollution problems in the United States: This Bureau of Mines report reviews the acid mine drainage problem generally and describes research currently underway to combat it.

INTRODUCTION

In the last 15 years there has been little improvement in the number of streams adversely affected by acid mine drainage. The Bureau of Mines has developed a comprehensive program of acid mine drainage research oriented toward both active and abandoned mines. It includes improved prediction of acid potential, improved mine planning, at-source control of acid formation, improved reclamation, improved water treatment techniques, and assessment of ground water contamination in major mining districts.

Controlling the acid at its source by limiting pyrite oxidation is a major objective of the program. The Bureau of Mines is investigating methods of slowing reaction kinetics by limiting oxygen, inhibiting iron-oxidizing bacteria, or otherwise influencing reaction chemistry. The Bureau has recently developed and field-tested a practical method of bacterial inhibition which is effective in reducing acid drainage from coal refuse piles. Since this technique is probably not applicable to abandoned underground mines, improved methods of mine sealing are required.

Bureau of Mines research into treatment of acid mine drainage is oriented toward improving water treatment efficiency and developing low-maintenance treatment systems. Current areas of investigation include improved iron oxidation efficiency, limestone neutralization, disposal of acid mine drainage sludge, and development of an artificial bog treatment system.

THE ACID MINE DRAINAGE PROBLEM

Acid drainage from underground coal mines and coal refuse piles is one of the most persistent industrial pollution problems in the United States. Pyrite in the coal and overlying strata, when exposed to air and water, oxidizes, producing ferrous ions and sulfuric acid. The ferrous ions are oxidized and produce an hydrated iron oxide (yellowboy) and more acidity. The acid lowers the pH of the water, making it corrosive and unable to support many forms of aquatic life. The iron oxide forms an unsightly coating on the bottom of streams, and further limits the ability of aquatic life to survive in streams affected by acid mine drainage.

Before coal is mined, very little of the pyrite is exposed to the conditions necessary to produce acid drainage. The mining and coal cleaning process exposes the pyrite to surface or ground waters and allows pyrite oxidation to occur. A ton of coal containing 1 pct pyritic sulfur has the potential of producing 33 pounds of yellowboy and over 60 pounds of sulfuric acid. However, the rate of acid production varies, and abandoned mines and refuse piles can produce acid drainage for more than 50 years. The drainage, if discharged into surface streams or ponds, constitutes an extensive, expensive, and persistent

FIGURE 1. - Ground water percolating through pyritic material produces sulfuric acid and iron compounds which are eventually discharged into surface streams.

environmental problem (fig. 1). Federal law (37)[5] now requires that water discharge from active coal mines have a pH between 6 and 9 and places limits on the total iron, manganese, and suspended solids. Controlling acid mine drainage from active mines usually requires expensive water treatment and the necessity of handling very large volumes of water. Controlling drainage from abandoned mines is even more difficult due to location, water volume, and the general limitation on public funds available for work in this area. The Bureau of Mines research program in acid mine drainage addresses the problems of both active and abandoned mines.

In 1936, it was estimated (17) that more than 9 million tons of sulfuric acid were discharged annually from coal mines into the streams of Pennsylvania. Now, although Federal and State regulations specify water quality standards for coal mine discharges, acid mine drainage remains a problem. The most comprehensive survey of the extent of acid mine drainage pollution was conducted by the Federal Water Pollution Control Administration in 1967 (2, 8). Drainage basins throughout the Appalachian Region, in Pennsylvania, West Virginia, Maryland, Ohio, Kentucky, Virginia, Tennessee, Alabama, and Georgia, were sampled for various water quality parameters including acidity, to determine the extent of water pollution caused by coal mine drainage. At that time, 10,500 miles of streams were significantly degraded by coal mine drainage, and further analysis of the data showed that approximately half, or 5,740 miles was affected by acid mine drainage (11).

Since that time, no Federal agency has undertaken a survey of this scale; current mine drainage assessments are restricted to statewide estimates. Direct comparisons between current State data and those collected in the 1967 study cannot be made, because of differences in the intensity of sampling and variation in the criteria used to classify a stream as degraded. However, current water quality data, obtained from State environmental agencies of the Appalachian Region, do indicate that there has been little overall improvement in streams affected by acid mine drainage.

In Pennsylvania, which annually produces approximately 82 million tons of coal (22), there are 2,795 miles of major streams that fail to meet current water quality standards (32). Drainage from abandoned mines contributes to at least 70 pct of the total. Although projected figures for 1983 indicate a slight decrease in stream miles that will not meet water quality standards, no decrease in the drainage pollution related to mining is expected.

In Ohio, where annual coal production was nearly 42 million tons (22), a 1979 study conducted by the Ohio Environmental Protection Agency indicates that acid mine drainage affects 1,075 miles of streams (30). In Maryland, where annual coal production was just over 2-1/2 million tons (22), the Maryland Bureau of Mines currently estimates that 450 miles of streams are affected by acid mine drainage (9), much of it related to mining in neighboring States. In Tennessee, where annual coal production is nearly 11-1/2 million tons (22), acid mine drainage was estimated to affect 994 miles of streams, according to the Division of Water Quality Control of the Tennessee Department of Public Health (35). In Kentucky, the Department for Natural Resources and Environmental Protection, Division of Abandoned Lands, has compiled data for 1978-80 which show that of a total of more than 2,100 miles of streams within the Eastern Coalfield affected by coal mine drainage, only 77 miles are acid (12). The low proportion of acid streams in this area of Kentucky is apparently related to the abundance of limestone in the coal-bearing rocks.

Although rigorous comparisons cannot be made, the more recent data indicate that the extent of acid mine drainage

[5]Numbers in parentheses refer to items in the list of references at the end of this report.

pollution is of the same order of magnitude as that measured in the 1967 study. Government regulation has done much to upgrade the quality of discharges from active mining operations, but most acid mine drainage comes from abandoned mines, which are not regulated. In spite of increased efforts to control it, acid mine drainage continues to be a major problem.

Present regulations stipulate that acid drainage from active mines and refuse piles must be chemically treated for as long as it is discharged from the mine or pile. These mandatory standards have generated research needs in the following areas: More efficient treatment methods, the disposal of sludge produced by treatment, engineering methods to reduce acid formation and other at-source methods of control, control of acid formation and erosion from spoil piles, and improved water management techniques. In addition, there is no systematic, cost-effective method of reducing the acid load from mines already abandoned and from mines to be abandoned in the future, although an estimated 80 pct of acid mine water comes from abandoned mines and spoil piles. This area particularly requires a concentrated research effort if there is to be significant improvement in the quality of many streams.

CHEMISTRY OF FORMATION AND CONTROL

Prevention and/or control of acid mine water depends on an understanding of the chemical, biological, and geological factors that influence its formation, which is best described as a series of chemical reactions. Acid mine water is produced by the oxidation of the pyrite (FeS_2) normally present in coal and the adjacent rock strata. The oxidation of pyrite is usually described by the reaction below in which pyrite, oxygen, and water form sulfuric acid and ferrous sulfate:

$$2Fe_2 + 7O_2 + 2H_2O = 4H^+ + 2Fe^{2+} + 4SO_4^{2-}.$$

Oxidation of the ferrous iron produces ferric ions according to the following reaction:

$$2Fe^{2+} + 1/2\ O_2 + 2H^+ = 2Fe^{3+} + H_2O.$$

When the ferric ion hydrolyzes, it produces an insoluble ferric hydroxide (yellowboy) and more acid:

$$Fe^{3+} + 3H_2O = Fe(OH)_3 + 3H^+.$$

Although this summary is correct at pH above about 4.0, it is only one of three different reactions systems, which vary in significance with pH (14). Also significant in the oxidation of pyrite is a bacterium, Thiobacillus ferrooxidans.

At near-neutral pH (stage 1), the rates of oxidation by air and by T. ferrooxidans are comparable. This stage is typical of freshly exposed coal or refuse. Despite the high concentration of pyrite, the rate of oxidation either by oxygen or by T. ferrooxidans is relatively low, and the natural alkalinity of ground water may effectively neutralize the acid formed at this stage.

When the neutralizing capacity of the environment is exceeded, acid begins to accumulate and the pH decreases (stage 2). As the pH decreases, the rate of iron oxidation by oxygen also decreases. But at the lower pH of stage 2, the rate of iron oxidation by T. ferrooxidans increases. The action of the bacteria causes increased acid production, which serves to further lower pH (fig. 2).

As the pH in the immediate vicinity of the pyrite falls to less than 3, the increased solubility of iron and the decreased rate of $Fe(OH)_3$ precipitation affect the overall rate of acid production (stage 3). At this point, ferrous

FIGURE 2. - In solutions inoculated with 0.2 ml of T. ferrooxidans (*A*) and 0.1 ml each of T. ferrooxidans and Metallogenium (*B*), the decrease in pH is greater than in sterile controls (*C*).

FIGURE 3. - Plot of acidity and total dissolved iron versus pH measured in laboratory simulations of a coal refuse pile shows the rapid production of acid and iron at low pH.

iron is oxidized by T. ferrooxidans and the ferric ion in turn oxidizes the pyrite:

$$FeS_2 + 14Fe^{3+} + 8H_2O = 15Fe^{2+} + SO_4^{2-} + 16H^+.$$

In this third stage, the rate of acid production is high (fig. 3) and is limited by the concentration of ferric ions. Inhibition of T. ferrooxidans would prevent ferric oxidation of pyrite and should therefore reduce acid production by at least 75 pct.

When untreated acid mine drainage is mixed with surface waters, it has a deleterious effect upon the receiving stream, usually making it unsightly and inhospitable to most forms of aquatic life. Most organisms cannot tolerate an acid environment. Also, the ferrous iron in acid mine drainage consumes the oxygen in a stream, and the precipitated ferric hydroxide covers the streambed, limiting the oxygen available to benthic organisms. The acidity and total solids adversely affect aquatic life, and heavy metal ions present in some mine waters have an increased toxicity in acid solutions (6). In streams severely polluted with acid mine drainage, there are usually no complex aquatic plants, no fish, few if any benthic invertebrates, and only a few species of algae. In some cases, the invertebrates and algae that can survive grow to nuisance proportions.

When acid mine drainage is produced in an active mine, environmental laws require that it meet minimum standards before it is discharged into surface streams. According to the Federal Water Pollution Control Act, water from coal mines must have a pH between 6 and 9 and must contain no more than an average of 3.5 ppm and a maximum of 7 ppm iron, no more than an average of 2 ppm and a maximum of 4 ppm manganese, and no more than 70 ppm total suspended solids.

Standard acid mine drainage treatment methods involve neutralization of the acid by the addition of a base, oxidation

of ferrous iron in an aeration tank or pond, and precipitation of iron compounds in a settling pond. Manganese, unless present in high concentrations, is usually removed with the iron.

The chemistry of the basic treatment method is relatively straightforward. Neutralization is the reaction of the acid with a base:

$$H_2SO_4 + Ca(OH)_2 = CaSO_4 + 2H_2O.$$

If limestone is used as the neutralizing agent, the reaction is

$$H_2SO_4 + CaCO_3 = CaSO_4 + H_2O + CO_2.$$

To remove the ferrous iron, the neutralized water is aerated to produce ferric ions, which react with the base to form insoluble ferric hydroxides:

$$Fe_2(SO_4)_3 + Ca(OH)_2 = Fe(OH)_3 + CaSO_4.$$

With limestone as the neutralizing agent, the reaction is

$$Fe_2(SO_4)_3 + 3CaCO_3 + 3H_2O = 2Fe(OH)_3 + 3CaSO_4 + 3CO_2.$$

Other alkaline agents can be used, but because of cost, ease of handling, or other environmental effects, lime is most commonly used. Other methods that have been suggested for treating acid mine drainage include reverse osmosis, ion exchange, and flash distillation. However, these are not treatment methods per se, but methods for producing potable water that were suggested for acid mine drainage only where there is no alternative source of potable water. With these methods a concentrated acid brine or sludge must be disposed of, and because of technical problems and high cost, processes like these are not commonly considered as reasonable alternatives to neutralization.

BUREAU OF MINES ACID MINE DRAINAGE RESEARCH

Methods to reduce the pollution from ferruginous acid water from coal mines and spoil banks usually involve either reducing the rate of acid formation or increasing the efficiency of mine water treatment. Although acid mine drainage has been a problem for many years, there have been few significant innovations in its prevention and control. The Bureau of Mines was involved in much of the acid mine drainage research conducted before 1970 (17, 20, 26). The Bureau performed analytical studies to determine the acidity, composition, and corrosivity of acid mine water. Sources of and variations in acid mine drainage, the effect of pyrite content, rock dusting, and chemical neutralization also were investigated. In addition, the Bureau of Mines was a major contributor to the development of mine seals during the 1930's.

During the 1970's the Bureau of Mines had only a limited acid mine drainage program as other Federal agencies, such as the Environmental Protection Agency (EPA), assumed primary responsibility for water pollution research. Because of the continuing problems in acid mine drainage control, the Bureau of Mines has recently developed a comprehensive program of acid mine drainage research. This program is directed toward several areas, including improved prediction of acid potential, improved mine planning, at-source control of acid formation, improved reclamation, improved water treatment, techniques to control acid drainage at abandoned mines and waste piles, and assessment of ground water contamination in major mining districts.

MINE SEALING

In 1928 it was reported that mines sealed by natural caving produced less acid than unsealed mines in the same locality (19). It was assumed that limiting the amount of air and water entering the mine reduced the rate of acid formation. After a 1-year field study, an extensive mine sealing program was undertaken in 1933 through the Works Progress Administration and the Civil Works Administration. Records indicate that sealing did produce favorable results in

West Virginia, Ohio, and Pennsylvania (36). However, the Federal sealing programs were short term and did not provide funds for maintaining the seals. Lack of maintenance, natural deterioration, vandalism, and subsequent mining combined to reduce the long-term effectiveness of the mine sealing program.

Despite the lack of long-term monitoring, mine sealing is considered a standard method for reducing acid formation from coal mines (27, 29). In mines located below drainage, natural flooding is used to cover the pyritic material and exclude air (fig. 4). When the air supply is eliminated, it is assumed that the pyrite is no longer oxidized. If the water pool is stable and the additional hydraulic pressure creates no downdip drainage problems, flooding is considered adequate.

This effect is currently being observed in the Northern Field of the Pennsylvania Anthracite Region (7), where flooded workings underlie approximately 43,000 acres. The Bureau of Mines is currently studying the hydrology and geochemistry of this large mine pool complex because the pool is well established, having started to form over 30 years ago. Owing to its size and flow characteristics, water draining from the mines remained acid until only a few years ago, casting some doubt on the effectiveness of flooding. However, our study has shown that the water in the mine pools has now recovered and is in fact slightly alkaline.

FIGURE 4. - In abandoned mines below drainage, natural flooding can be used to exclude air, limiting pyrite oxidation.

In deep mines above drainage, flooding is generally ineffective owing to seepage through surface fractures and the tendency of the water to migrate to other discharge points. In such mines, conventional seals are airtight and/or watertight masonry walls hitched into the roof, bottom, and ribs of mine openings (fig. 5). Subsidence fractures that extend from the mine through the caved overburden to the surface serve as open pathways for the migration of air and the drainage of surface water (fig. 6). To effectively seal these mines, it is also necessary to backfill and grade all fractures that extend from the mine to the surface. Although aerial photography and infrared scanning can be used to locate zones of high permeability, this process is expensive and not sensitive enough to delineate relatively small subsidence fractures. Indiscernible joints and subsidence fractures can affect the overall effectiveness of a mine sealing project by allowing a mine to "breathe" (fig. 7). Monitoring by the Bureau of Mines has shown a general correlation between the oxygen level in the mine, the differential pressure across mine seals, and changes in the barometric pressure (28).

Because most mine sealing evaluations are based on short-term observation, the Bureau is now evaluating the long-term effectiveness of mine sealing in several areas. For example, at Moraine State Park grouted double bulkhead seals were used in an area where an artificial lake was built over 10 years ago. In this area, water discharged from sealed areas has a total mean acid load of 206 lb/day 10 years after sealing, compared with 540 lb/day before sealing. The discharge rate varies between 250 and 500 gpm, and the total iron has a mean value of 53 lb/day at present, compared with 46 lb/day prior to sealing (21). Over the 10-year period the variation in discharge rate, acidity, alkalinity, and total iron has declined, indicating that a mine pool has been created as a result of sealing. In the Highland Fuel Mine area (Butler County, Pa.) water samples are obtained from discharge points and from observation holes behind the seals. The discharge from the sealed area varies from 25 to 80 gpm, and the pH of the water is approximately 4. Total iron in the discharge averages 12 to 14 ppm. Water samples from the mine pool behind the seals have an average pH above 6 and a higher total iron content.

Recent inspection of wet, dry, and hydraulic and/or bulkhead seals constructed 13 years ago in abandoned mines near Elkins, W. Va., has shown that five of the clay seals have deteriorated, allowing acid seepage to kill vegetation on the slopes below the seal. Yellowboy precipitate has restricted the drainage opening of one wet masonry block seal. Water quality in at least one stream receiving discharge from the sealed mines has not improved significantly since the mines were sealed.

The Bureau's evaluation of mine seals installed approximately 10 or more years ago has indicated several serious problems with conventionally constructed seals. First, completely sealing a mine above drainage is very difficult and may be very expensive. Complete sealing requires that all zones of high permeability be located and sealed. The usual procedure is to locate subsidence fractures, cover the area with a compacted clay blanket, and regrade it. To be effective, this procedure requires that all fractures be located and that no further subsidence occur. The evidence indicates that surface sealing is rarely effective for long periods. Another problem with mine sealing is that masonry seals require continued maintenance. Even if seals are adequately built and maintained, the improvement in water quality directly attributable to the sealing process has not been adequately determined.

To improve the effectiveness of mine sealing, the Bureau of Mines is studying sealed mines to determine factors controlling changes in water quality and is developing techniques to build more efficient, less expensive seals. In

FIGURE 5. - A wet seal with an air trap allows water to leave the mine while preventing air from entering.

FIGURE 6. - Subsidence cracks over an underground mine may allow surface water and air to enter a sealed mine.

FIGURE 7. - Although the oxygen level in a sealed mine may be lower than that of normal air, it may be sufficient to support oxidation for long periods of time.

addition to monitoring discharge rates and water quality parameters, at some sites drawdown testing will be used to determine aquifer capacity and water level fluctuations. Subsidence areas will be surveyed during and after drawdown testing. The collection of rainfall data and the use of fluorescent dye to determine the direction and velocity of ground water flow in the mine pool will also be used to determine the factors that affect water quality when mines are sealed conventionally.

The Bureau also is involved in a demonstration of pneumatic stowing of limestone as a method of producing more effective mine seals at a cost equal to or less than that of conventional seals. Observations of mine seals to date indicate that seals constructed of cement block and grout do not substantially improve water quality, may not effectively contain impounded water, and are subject to failure and/or leakage. The construction of a competent seal requires that it be permanently attached to the roof, ribs, and floor. Frequently the failure of conventional seals is due to collapse of weak strata over the seal. Pneumatic stowing produces a highly compacted limestone plug which supports roof and ribs. Movement of surrounding strata will cause further compaction of the limestone. Concrete or other additives to the limestone can be used to produce a stronger seal. If appropriate, the limestone seal can be constructed to allow low flows of mine water. If the water is only slightly acid, passage through the limestone can effectively neutralize it. In a field trial of pneumatic stowing, the limestone seals were found to be satisfactory in terms of the safety of construction, the strength of the seal, and the cost. Long-term monitoring of these seals is planned to determine their effect on water quality.

In deep mines, the construction of mine seals limits the water discharge rate and creates a mine pool covering some or all of the pyritic material. If inundation is to be an effective method of controlling acid drainage, outcrop barrier pillars must be capable of withstanding the hydrostatic head created by the impounded water. In general, Federal and State regulations on mine closure do not deal directly with criteria for outcrop barriers used to flood the mine. A Bureau of Mines contract report (31) details the factors that affect the competency and stability of outcrop barriers. According to the study, an outcrop barrier should be wide enough to prevent seepage, have sufficient overburden to prevent a blowout, and provide a stable slope. Curtain grouting, compartmentalized barriers, and relief wells can be used to reinforce outcrop barriers.

In mines that have been successfully inundated, water quality is often good in the mine pool but generally acid after seeping through the barrier. Use of a relief well system, as suggested in the contract report (31), would remove water from the mine pool prior to its exposure to pyrite-bearing coal and would also limit the hydrostatic head that the outcrop barrier would have to withstand. Properly designed outcrop barriers could

reduce acid formation in abandoned mines and allow maximum coal removal.

Oxygen may also be a limiting factor in coal refuse piles and some surface mines. The Bureau of Mines is currently using soil gas probes to study oxygen diffusion characteristics in coal refuse piles; preliminary results indicate that pyrite oxidation is limited to a near-surface layer. A similar study will soon be initiated in an abandoned surface mine. Followup research will concentrate on current reclamation methods to determine if any reduce oxygen diffusion or result in the consumption of oxygen, thus limiting acid formation.

ACID MINE DRAINAGE TREATMENT

Many factors influence the quantity and quality of water handled by a mining operation, but it is not unusual for a single mine to treat 1 million gallons of acid water per day. Water from coal mines is usually treated by chemical neutralization. At present, lime is the most commonly used neutralizing agent. Generally, a small volume of mine water is added to powdered lime to produce a slurry which, added to the raw mine water, raises the pH to between 7 and 9. The water is aerated to oxidize the ferrous iron and is then transferred to a settling pond for precipitation of the iron compounds (fig. 8). Although commonly used, lime neutralization has several inherent problems. Lime is a caustic material and can produce water with an unacceptably high pH. Lime treatment produces a flocculant precipitate that does not form a dense, easily handled sludge. Research by EPA failed to produce any economical improvement in sludge disposal methods. The Bureau is evaluating the technology and economics of current sludge disposal practices to determine the most promising area of research. Sludge disposal problems, and high cost (fig. 9) are the principal reasons for seeking improved acid mine drainage treatment methods.

FIGURE 8. - Flow diagram of hydrated lime treatment process for acid mine drainage (34).

FIGURE 9. - Although the unit cost decreases with capacity, the total capital costs may range between $500,000 and $2 million for a conventional treatment process (34).

As an alternative treatment method, the Bureau has developed a neutralization process using limestone instead of lime (4, 6, 14, 17, 24-25). Limestone is readily available and costs less than lime, and limestone treatment produces a dense crystalline sludge (fig. 10). In the Bureau treatment process, very fine (5 to 10 μm) limestone is produced by wet autogenous grinding in a tube mill. The limestone slurry is mixed with the acid mine drainage, and the drainage is aerated to remove carbon dioxide and to oxidize the ferrous iron (fig. 11). The gypsum-iron oxide sludge separates from the drainage in settling ponds. Although limestone treatment has the advantages of lower material costs, simplicity of plant design and operation, the use of a less hazardous material, and a denser sludge, its use is limited by the rate at which ferrous iron is oxidized. With limestone neutralization, the pH of the treated drainage is between 6.8 and 8.0 and the iron oxidation rate ranges from 10 to 25 ppm/min (fig. 12).

FIGURE 10. - Limestone treatment produces a denser sludge in 1 day than lime neutralization produces in 43 days.

To minimize the power and land requirements for aeration, the Bureau is investigating the use of catalysts to increase the rate of ferrous iron oxidation at low pH. A laboratory study by the Bureau of Mines indicated that activated carbon was an effective catalyst in the oxidation of ferrous iron (23). In batch tests, the ferrous iron content of acid mine drainage flowing through an aspirated column of activated carbon was reduced from over 700 ppm to less than 10 ppm in approximately 1 minute. In these tests, approximately 5,000 ml of the acid drainage was passed through the 200 grams of activated carbon before the catalytic effect was noted. During this period the pH of the effluent was higher than that of the mine drainage feed. Since the increase in iron oxidation rate was observed after the pH of the drainage showed substantially no change, the onset of the catalytic effect was attributed to acid conditioning the carbon.

A pilot-scale field study was conducted (33) to study the effect of activated carbon on the ferrous iron oxidation rate using a three-stage continuously stirred reactor. Continuous agitation of the carbon in the mine water provided more efficient water-carbon contact and prevented channeling and/or fouling. A weir device at the top of the reactor controlled carbon loss. In this system the ferrous iron oxidation rates were not as high as those reported in the previous laboratory study. Acid conditioning the carbon did not significantly affect the iron oxidation rate. When the pH of the influent water was adjusted to 5, the rate of iron oxidation increased, but not to the levels reported in the laboratory study. When comparing the rate data from the field and laboratory studies, it was considered possible that the high iron oxidation rate reported was due to the growth of iron-oxidizing bacteria on the carbon rather than to direct catalysis by the carbon. T. ferrooxidans is an aerobic bacterium which derives energy from

FIGURE 11. - Limestone treatment, which includes neutralization, aeration, and settling, is less expensive and produces a dense crystalline sludge.

the oxidation of ferrous iron in acid mine drainage. It is possible that the activated carbon provides a substrate to which the bacteria adhered. However, recent laboratory tests showed no significant bacterial activity or catalytic action.

The Bureau is also funding an investigation of the growth of iron-oxidizing bacteria on clay particles (5,000 mg/l) in a sequencing batch reactor. In this test bacteria are grown on clay particles in a ferrous sulfate solution containing appropriate inorganic nutrients. The reactor, a system of fill, aerate, settle, and discharge cycles (fig. 13), is designed to produce an effluent with a Fe^{2+} concentration of less than 10 mg/l. The retention of bacteria on the clay particles is dependent upon the ferrous iron content. If the Fe^{2+} content of the system decreases to 5 mg/l, the bacteria are desorbed from the clay and removed from the reactor in the discharge cycle. Using the sequencing batch reactor, a ferrous iron oxidation rate of approximately 290 mg/l/hr has been reported for estimated bacterial populations of approximately 5×10^7 cells/ml.

The disposal of sludge produced by neutralization of acid mine drainage is expensive and potentially one of the most persistent problems in its treatment. As a preliminary step, the current sludge disposal practices of 33 treatment plants were assessed to determine the magnitude of sludge production, current disposal practices, and constraints on their usage (1). The primary sludge disposal problem involves the large volume of sludge generated and the scarcity of approved disposal sites. The four most commonly used

FIGURE 12. - In acid mine drainage neutralized with limestone, the rate of ferrous iron oxidation is 10 to 25 ppm/min.

FIGURE 13. - The sequencing batch reactor incorporates fill, aerate, settle, and discharge cycles to optimize the rate of ferrous iron oxidation by bacteria.

methods of sludge disposal are deep mine disposal, retention in ponds, incorporation in coal refuse piles, and surface burial. The amount of land required for disposal is usually the determining factor in the overall cost, although transportation, equipment, maintenance, and labor are also significant (fig. 14). The development of methods to efficiently and economically increase the density of the sludge would substantially reduce the cost of sludge disposal.

Although there are other methods potentially applicable to acid mine drainage

FIGURE 14. - Most sludge from acid mine drainage (AMD) treatment is retained in ponds, pumped into abandoned sections of deep mines, or dumped in refuse areas.

treatment, such as ion exchange, reverse osmosis, and flash distillation, the Bureau is not currently investigating these. Most of these processes are high in cost, have high power requirements, and produce a highly concentrated toxic brine or sludge which is more difficult to dispose of than the original sludge. The Bureau's research program in treating acid drainage from active mines is directed toward development and demonstration of a complete limestone treatment system, including a suitable catalyst for rapid oxidation of ferrous iron and sludge disposal.

The Bureau is also investigating a low-cost, low-maintenance treatment system for small streams contaminated by acid drainage from abandoned mines. Conventional treatment is not applicable because of the low flow rate and the remote rural location. It has been observed that bogs containing sphagnum moss and/or cattails remove iron by ion exchange and precipitation (10). Subsequent neutralization at limestone outcrops completes an effective natural treatment system. Artificial duplication of this natural process could improve water quality in many small streams.

The Bureau will test the practicality of duplicating this natural treatment system at a low-flow acid drainage discharge point in Northern Appalachia.

The system will include an artificial sphagnum moss bog followed by limestone rubble. The system is designed so that the drainage will pool in the moss, but will not raise the upstream water level enough to allow the water to flow around the treatment system. Monitoring the pH, Eh, temperature, iron and sulfate concentrations, and total acidity of the stream above and below the artificial bog will determine its effect on water quality. The monitoring will extend over at least 6 months so that the effect of uncontrollable parameters such as ambient temperature, rainfall, and stream flow rate can be determined. If this low-cost, low-maintenance system proves to be effective, it could be used to restore many small streams in rural areas.

AT-SOURCE CONTROL OF ACID MINE DRAINAGE

Of the millions of dollars spent on acid mine drainage each year, the major portion is spent on treatment. But treatment is not the best solution to most acid mine drainage problems. Treatment has the disadvantage of being necessary for as long as the acid discharge continues and thus requires manpower, surface facilities, and a sludge disposal area indefinitely.

Since acid drainage results from the oxidation of pyrite associated with coal and overburden strata, limiting the rate of pyrite oxidation would reduce the amount of acid formed. T. ferrooxidans normally catalyzes the pyrite oxidation and accelerates the initial acidification of freshly exposed coal and overburden. Inhibiting bacterial activity, therefore, would limit the rate of acid production and, in combination with proper reclamation, would reduce substantially the total amount of acid produced. Of the multitude of potential bactericidal agents, certain biodegradable anionic surfactants (detergents) have been found to control T. ferrooxidans in an economical and environmentally safe manner (15).

Field tests were recently conducted by the Bureau of Mines on both active and abandoned coal refuse piles in West Virginia (16). Sodium lauryl sulfate was applied at rates of 20 to 55 gal of 30-pct solution per acre, with a dilution range between 1:100 and 1:1000. Application rates were based on laboratory adsorption tests; dilution rates were dictated by site characteristics. At each site, drainage pH rose from approximately 2.5 to 5.5 or higher, with similarly dramatic decreases in acidity, iron, and sulfates.

One disadvantage of the detergents is that their effectiveness is limited; repopulation of the bacteria typically occurs in 3 to 4 months. To provide long-term control, the surfactants have been incorporated into rubber pellets (16) which can be applied early to a refuse pile or pyrite mine spoil. These pellets gradually release the surfactant into infiltrating rain water. In laboratory studies (fig. 15) and pilot-scale tests (fig. 16), controlled release of sodium lauryl sulfate reduced acid production 50 to 95 pct (14). Full-scale field tests are now in progress.

Another potential approach to at-source control of acid production requires the establishment of an alkaline environment. As already discussed, pyrite oxidation is

FIGURE 15. - The rate of acid production was approximately that of sterile controls when detergent was used to limit bacterial activity in a laboratory study.

FIGURE 16. - Controlled release of detergents can be used to reduce acid production from spoil piles by 50 to 95 pct compared with an untreated control.

slow at near-neutral pH. A source of alkalinity such as lime, if added to recently exposed pyritic material, will retard or prevent acidification. The Bureau of Mines is currently investigating the possibility of reestablishing a radically alkaline environment, albeit temporarily, to determine if this will slow pyrite oxidation to the point where limestone will be sufficient to maintain near-neutral pH.

Water handling procedures for underground coal mines generally combine gravity flow and collection with pumping from sumps to surface treatment and/or disposal areas. To minimize the formation of acid water, properly placed sumps and pumping systems can reduce the time the water is in contact with pyritic materials. The size and location of sumps is also governed by the ability to discharge water on the surface with minimum power. Since on the average it requires 0.5 kwhr to pump 1,000 gal of water against a 100-ft head, gravity drainage and an efficient pump are most cost effective. The capacity of water treatment facilities depends upon flow rate and the concentration of pollutants. In designing a treatment system, using infiltration control and efficient water handling to reduce the amount of water flowing through the mine and minimize the amount of acid formed can result in substantial savings in water treatment costs.

A recent Bureau of Mines contract study examined current state-of-the-art methods of water diversion and overburden dewatering in Appalachian bituminous coalfields (3). It was found that most water enters underground mines either through water-bearing strata in contact with the coal seam, from surface seepage, through faults and fractures, or from abandoned workings. If surface water is the source, runoff diversion, regrading, soil sealing, and streambed modifications are possible control methods. The influx of ground water may be controlled by reducing the permeability of overlying strata, sealing abandoned mines, and well dewatering in advance of mining. Although all of these methods have been tried to some extent (table 1), their successful application depends largely upon geologic and hydrologic conditions. In general, the standard approach to handling the influx of water into underground mines consists of collecting the water and pumping it back to the surface. At present it appears that water diversion and overburden dewatering are, at best, supplements to traditional water handling procedures. Such methods have the advantages of helping to control large influxes of water that could affect production and reducing the cost of water treatment.

TABLE 1. - Water control practices (2)

Water control practice	Application	Limits of control	Field experience
	SURFACE WATER CONTROLS		
Runoff diversion...	Prevents infiltration into soil, mine openings, outcrops, rock fissures, strippings, cave-ins, surface cracks, and subsidence areas.	Effective if mine inflow is due to infiltration. May increase stream flow.	Used with varying success.
Surface regrading..	Eliminates ponding and improves drainage. Applicable near surface mines or other large land disturbances.	Depends on drainage area, annual precipitation, rate of infiltration into soil. May increase stream flow.	Used at strip mine sites. Can be very effective if mine water is due to ponding of water over mine.
Soil sealing.....	Prevents infiltration into soil by reducing permeability.	Prevents infiltration into soil only. Not effective in sealing fractures or other flow conduits.	Limited success.
Stream channeling..	Prevents inflow to mines from streams, especially in areas of vertical fractures, subsidence, or high permeability.	Can prevent large quantities of water from entering a mine.	Very effective.
	GROUND WATER CONTROLS		
Grouting and/or grouting curtains.	Reduces permeability of overlying strata by sealing fissures, fractures, and permeable formations.	Effective in limiting inflow via direct conduits.	Effective in curtailing water inflow during shaft sinking. Also used to cement localized areas of water inflow such as faults and joints.
Borehole sealing...	Prevents inflow to mines through boreholes from surface water sources and/or overlying aquifers.	Sealing ineffective after roof collapses.	Effective in reducing inflow through boreholes.
Subsurface soil sealing.	Prevents infiltration through the soil by reducing permeability.	Sealing efficiency reduced if area fractured. Most sealants are uneconomical.	No demonstrations of this technique.
Mine sealing.....	Prevents water from escaping an abandoned mine and infiltrating active workings.	Seals may lose effectiveness with time, depending on construction method and strata changes. Seals may cause ground water levels to rise, causing surface damage. Breached seals may prove hazardous to adjacent operating mines.	Effective in reducing or eliminating flow from abandoned mines into active mines.
Well dewatering....	Intercepts aquifers and controls the movement and discharge of groundwater.	Requires favorable geologic conditions.	Limited success. Used in reducing water handling requirements in mine.

In coal mines where fracture-dominated inflow is localized, intercepting water entering through faults and fractures may be feasible. Water flowing through such fracture zones is essentially surface water and would not normally require treatment. The Bureau has awarded a contract to conduct a pilot study on controlling fracture-dominated inflow. The study will develop design criteria for, and determine the cost effectiveness of, intercepting nonacid water flowing through localized fractures and transporting it to the surface. Economic and engineering analysis of this process should determine if it would reduce the cost of treatment substantially.

Coal storage piles and refuse piles may also be sources of ground water contamination (38). Rainfall percolating through such piles may leach acid and/or other toxic ions and carry them into ground water. The Bureau has awarded a contract to assess the extent of ground and surface water contamination from coal storage piles. Methods to prevent contamination of ground water include surface collection, impoundment, and treatment of runoff water. Preliminary cost estimates and a discussion of beneficial and adverse effects will be included.

Another area of concern is the effect of large-scale lignite mining in western Tennessee on ground water resources. At present there are few data available on the effects of mining upon ground water in the alluvial plain, in both shallow and deep aquifers. To gather data, four wells and two pits have been dug to determine ground water levels, movement, and chemistry. A contract report will assess the hydrologic impact of lignite mining.

SUMMARY AND RECOMMENDATIONS

The Federal Water Pollution Control Act of 1972 set effluent standards for coal mines, requiring treatment for acid mine drainage. Although these standards have been in effect for almost a decade, there has not been significant improvement in the water quality of many streams affected by mine drainage. This lack of improvement is related to the amount of acid drainage flowing from abandoned mines.

It has been known for years that air, water, bacteria, and pyrite are essential elements in acid production, yet at present there is no standard method or program for limiting the formation of acid mine drainage. Controlled release of anionic surfactants appears to be applicable to near-surface sources of acid production but not to long-term treatment of underground mines. Mine sealing, which is supposed to limit acid production in abandoned mines, has been only marginally successful (table 2). Bureau of Mines studies indicate that surface reclamation and seals at mine openings do not retard the passage of air into a mine. In many cases, seals used to flood a mine or the surrounding strata cannot withstand the continuous hydraulic pressure, resulting in failure of the seal or seepage around it. The Bureau is now evaluating mine seals in several areas in order to determine relevant chemical, geological, and engineering parameters and to determine the long-term effect of mine sealing on water quality.

Mine sealing is relevant not only to abandoned mines, but also to operating mines that will close in the future. At the present, mines must eliminate acid production or treat acid drainage indefinitely. It is possible that bond forfeiture may become a realistic economic alternative to the long-term cost of water treatment. In this area, there is need for development of low-cost seals that will maintain their integrity indefinitely. Other methods such as controlled roof collapse, water diversion, bacterial inhibition, and improved drainage should be investigated to determine their usefulness in reducing the formation of acid in mines that are no longer operating.

TABLE 2. - Variation in composition of mine effluent before and after sealing

	Mine 1				Mine 2			
	Before		After		Before		After	
	Low	High	Low	High	Low	High	Low	High
pH	2.9	3.2	3.0	5.5	2.3	3.2	2.85	3.70
Total acidity (as $CaCO_3$)[1] ppm	75	1,290	45	490	80	1,210	20	1,170
Sulfate (as SO_4) ppm	655	2,260	356	1,180	349	2,520	152	2,375
Calcium (as $CaCO_3$) ppm	203	1,242	36	625	125	760	70	725
Magnesium (as $MgCO_3$) ppm	109	520	76	336	76	530	7	502
Total iron (as Fe_2O_3) ppm	13	508	5	160	33	670	23	720

[1]End point = pH 8.2 at 60° C.

Improved prediction of acid drainage potential is being investigated in order to eliminate or minimize the formation of acid mine drainage. At present, core samples are analyzed for total sulfur and potential alkalinity, or tested with slow leaching methods. These procedures have not been correlated with acidity measurements in the field, and they are generally acknowledged as only an approximation of potential acid problems. Available techniques will be tested at sites where the extent of acid production is known, to determine their accuracy and possibly develop modifications. Rapid-leaching tests will also be examined for their applicability to the determination of acid potential. Accurate methods of predicting acid potential of coal and overburden will allow better permitting by State agencies, improved mine planning, and improved reclamation.

In operating mines, the need to treat large volumes of acid drainage is a problem. Currently, lime neutralization with aeration is the standard method of treating acid mine drainage. This method is relatively expensive, requires handling a caustic substance, and produces a sludge with poor settling characteristics. The Bureau has developed and is now improving a treatment system using limestone. Limestone treatment is less expensive, uses a noncaustic material, and produces a denser sludge. Routine use of the system requires the rapid oxidation of ferrous iron at acid or neutral pH. In an initial field study, activated carbon did not have the anticipated catalytic effect on the iron oxidation rate. Presently, studies are underway to determine if iron-oxidizing bacteria grown on activated carbon can increase the rate of iron oxidation in acid mine drainage. A study using bacteria grown on clay particles in a sequencing batch reactor has the same purpose. The develop-ment of an effective oxidation step will allow full-scale testing of the limestone treatment process. At present, other methods of treating acid mine drainage are not economically or technically practical. Limestone treatment seems to be one alternative that could be technically feasible and economically superior to lime treatment, although at present it is primarily applicable to waters with a low ferrous iron content. It also has the advantage of being readily adaptable to reclaiming streams affected by drainage from abandoned mines. A passive system using sphagnum moss and limestone will be tested as a means of improving water quality in low-flow streams.

It is apparent that 10 years of mandated water treatment have not produced a significant improvement in overall water quality. Although treatment of acid drainage from active mines prevents further deterioration, the majority of mine water pollution originates from abandoned mines. At present there is a need to develop methods for reclaiming polluted streams and for at-source control of acid production. Research is needed to

develop limestone treatment into a practical alternative to lime neutralization. To address these and other acid mine drainage pollution problems, the Bureau of Mines is conducting research in bacterial inhibition to control acid generation, improved water handling to reduce acid load, development of improved mine seals, rapid biological oxidation of ferrous iron, improved sludge disposal practices, low-maintenance treatment of small streams, reclamation techniques to reduce acid drainage formation, and limestone treatment of acid drainage (table 3).

Work in these research areas comprises a comprehensive approach to solving many of the longstanding problems associated with acid mine drainage. Improved treatment methods, at-source control methods, and stream reclamation methods resulting from the Bureau's research program will make a significant contribution to upgrading water quality in mining areas.

TABLE 3. - Bureau of Mines conservation and development program--acid mine drainage

Research area	Proposed time frame, fiscal years
Prediction of acid mine drainage:	
Prediction of acid potential	1981-85
Prediction of water infiltration	1981-84
Integration of predictive technology and premine planning	1984-86
At-source control technology:	
Inhibition of acid-forming bacteria:	
Surface mines and refuse piles	1981-83
Tailings piles	1983-84
Extension of bacterial inhibition to underground mines where applicable	1983-86
Alkaline treatment of coal refuse	1982-83
Placement of phritic overburden	1982-85
Water handling procedures, including diversion and dewatering	1981-85
At-source control technology for inactive or abandoned mines:	
Daylighting	1982-85
Effect of flooding on acid production, limiting parameters	1982-85
Improved mine seals	1981-86
Feasibility study--underground disposal mine refuse in a flooded mine	1982-83
Demonstration of above if feasible	1984-85
Reclamation of acid seeps (burnout) on revegetated mine sites	1982-85
Water treatment:	
Enhanced oxidation of iron	1981-86
Limestone neutralization	1984-86
Improved sludge disposal	1982-84
Assessment studies:	
Ground water contamination by acid-producing metal ore mines and tailings ponds	1982-86
Economic analysis--recovery of metals from tailings or streams	1983-85
Manuals:	
Premine planning to minimize acid drainage	1985-86
At-source control of acid drainage	1985-86

QUAKAKE TUNNEL DEMONSTRATION PROJECT
LIMESTONE NEUTRALIZATION OF AMD

At some point in time, under very selective circumstances, construction and operation of an AMD treatment plant might be unavoidable. When either active or abandoned mining has been developed to a stage where the groundwater is a vast polluted mine pool and the surface waters are contaminated beyond use, treatment of AMD will be required to meet clean water needs. Treatment may not be the whole solution, but it will be a costly part of the solution.

The Pennsylvania Department of Environmental Resources has constructed five major AMD treatment plants between 1970 and 1979 at a total cost of $14 million. These plants were funded by the State's $500 million environmental bond issue of 1967. Today, only two plants are operating (one only part of the year) at an annual operating cost of $535,000. All of these plants have been of the conventional wastewater treatment design utilizing either hydrated or pebble lime for neutralization.

We can sum up our experiences as follows:

1. Very high capital costs.
2. Very high annual operating cost.
3. Constant maintenance problems.
4. Very poor initial design.
5. Labor intensive operations.
6. Hydraulically undersized for peak flow conditions.
7. Sludge removal and disposal problems.
8. Low factor reliability.

In the mid-1970's the Department initiated a state-of-the-art search for limestone neutralization technology. We found much fragmented research and development completed. A demonstration project was then developed to test, refine, and compare current technology. The Quakake drainage tunnel from the abandoned deep mines of the Jeansville Basin in the middle anthracite coal fields was the selected site.

Our ultimate purpose was to develop design and operating criteria at the Quakake pilot plant for application to full scale plants. The object was to use existing research and technologies for the project development.

Various neutralization processes were designed upon theories developed and presented by Dr. F. Pearson's and Dr. A. McDonnell's "Use of Crushed Limestone to Neutralize Acid Waters." Static limestone beds of varying stone size, length, and energy gradients were tested. Vertical beds contained in columns, where hydraulic suspension of the bed for cleaning was possible, were tested. Also, an autogenous mill, which was a simple water wheel and rotating drum, was operated at various flow rates with different size and quality of limestone.

Our findings are that limestone neutralization is feasible, economical and the reliable treatment process. Limestone facilities will have a lower capital cost, lower reagent cost and be less labor intensive to operate. The handling and long-term storage of reagent, as well as reliability of a simple process control are built-in benefits. Sludge settling and dewatering characteristics are excellent to allow for landfill disposal of a solid cake.

Pennsylvania is developing plans to construct a full scale limestone pilot plant in the headwaters of Little Toby Creek, Elk County. This pilot plant will be operated and evaluated to prove the findings of the Quakake demonstration project. The results of its operation and evaluation will be the basis to determine if limestone neutralization will play a major role in the control of acid mine drainage in Pennsylvania.

Mr. A. E. Friedrich, Chief
Division of Mine Area Restoration
Bureau of Resources Programming
PA Department of Environmental Resources
P. O. Box 1467
Harrisburg, PA 17120

Dear Mr. Friedrich:

You contacted us sometime ago about the self-feeding limestone drum acid water neutralization system. This is an update on the testing of the proto-type station.

We had hoped to have testing completed this spring, but a number of small problems developed that will require another six months or so of testing. Enclosed is a performance report that will give you the current status of the project.

The testing scheduled for this winter and next spring will concentrate on maximizing production rates of $CaCO_3$ fines from the drum. Results may require some minor changes in blueprints and specifications for drum manufacture.

You will be contacted again next year and given the project status.

Sincerely yours,

Peter E. Zurbuch

ABSTRACT

This paper deals with the design of a treatment station for acidic streams using a self-feeding rotary limestone tumbling drum activated by the stream flow. It can operate unattended for seven to ten days while being supplied continuously at the required rate from a storage bin. Unique features of the self-feeding mechanism are presented here with experimental data that can be used in the design of high efficiency drums.

INTRODUCTION

The West Virginia Department of Natural Resources (WV DNR) pioneered the successful use of crushed limestone to neutralize lightly buffered acid streams [1]. The high-calcium limestone was tumbled within drums, equipped with water vanes, that were powered by stream flow. The drums were batch-loaded with 1,800 pounds of stone which was used up within four days at the maximum operating flow of 4.0 cfs. Each drum abraded an average of 20 pounds per hour of limestone fines into the stream at that flow. A treatment station of four such drums was operated from 1964 to 1979 on the headwaters of Otter Creek, a small mountain stream in the Monongahela National Forest of West Virginia. Neutralization of the streams acid flow permitted the establishment of a native brook trout (Salvelinus fontinalis) sport fishery [2].

In the 1970's West Virginia began to have increasing problems in stocking trout in some major trout streams because of spring acid conditions. Many of these waters were in watersheds that had no coal mining thus discounting acid mine drainage as a possible cause. Acidification appeared instead to be associated with acid precipitation. The decline in these fisheries approximated the increase in acid precipitation for eastern North America [3].

Treatment of the affected waters is beyond the capabilities of the batch-loaded "limestone drums". Previous experiments with the drums indicated their efficiency in producing limestone fines could be increased if they were operated partially filled. To be feasible for use in stream neutralization, operating a partially filled drum would require external stone storage and a method to feed the stone into the rotating drum. It was felt that this type system would have the advantages of increasing the amount of limestone fines being produced while reducing the servicing requirements.

A test of this hypothesis was conducted by the WV DNR in 1980. A batch-loaded drum was tested containing only 10 percent of its capacity of stone. At one-half intervals the drum was stopped and a small amount of stone added. The test showed a dramatic increase in the amount of limestone fines being dissolved into the stream. It also indicated the drum would stabilize itself so that the rate of limestone was equaled the rate of stone being fed into the drum. A research project was then initiated to develop a second generation limestone drum system that would be self-feeding. The WV DNR entered into a cooperative research endeavor with the Mechanical and Aerospace Engineering Department at West Virginia University to design and test such a system. This paper presents the results of this effort.

1. SELF-FEEDING WATER POWERED LIMESTONE DRUM SYSTEM

In Figure 1 the principal components of the self-feeding water powered limestone drum system are shown. The system consists of a rotating drum with waterwheel blades that is activated by falling water through an opening at the bottom of the sluice. The limestone aggregates that are stored in a 10-ton gravity bin and hopper are fed to the rotating drum through the action of a reciprocating feeder at the bottom of the storage bin. After falling through a chute they are transported in a hollow shaft with internal helical blades acting as a screw feeder. A flexible drive shaft is used to convey directly power from the rotating drum shaft to the reciprocating feeder through two speed control units. A calibrated opening in the reciprocating feeder acts as a metering device to control the amount of aggregates that can be fed to the chute after each stroke of the feeder.

With this arrangement the feed mechanism can be compared to a feedback control system providing the exact amount of aggregate to the drum for any flow rate of the stream. When the rate is high the drum turns faster, the number of strokes of the reciprocating feeder per unit time increases, and hence more aggregate is supplied to the drum. The opposite happens when the stream flow is low and less amount of aggregate is needed in the drum. Metering the flow of limestone to the drum in this way, at the exact pre-determined rate for the corresponding flow rate of the stream, keeps the desired value of the pH level constant in the water, regardless of flow conditions.

The action of the limestone aggregates in the revolving drum is a wet autogeneous process. Falling water through sluice opening enters the drum on top through small holes in the shell of the drum between the water wheel blades, and after mixing with (-400) mesh limestone particles already generated through the tumbling process in the drum, leaves it through the same holes at the bottom position where it is discharged to the stream for acid neutralization.

1.1 Main Features of Principle Components

All components of this neutralization station are designed with the primary objective of providing trouble-free operation requiring very little supervision and operator assistance.

1.1.1 10-Ton Storage Bin

The square pyramidal bin with 60 degree hopper angles can store a one week supply of limestone of 1¼ in. size for acid stream treatment. The bin provides continuous gravity flow of limestone particles at the rate of 120 lb/hr. to the reciprocating feeder through a 15 in. square opening. The bin geometry was determined after considering the flow characteristics of limestone aggregate

SELF-FEEDING
WATER POWERED
LIMESTONE DRUM

FIGURE 1

in the bin, its density, angle of repose, and possible resultant loads on the reciprocating feeder. Also of prime importance was the height of the bin which was desired to be kept at minimum for the required capacity. This height is within the reach of a front loader that can be used by an operator to load the bin once a week most economically.

1.1.2 Reciprocating Feeder

Main features of the reciprocating plate feeder in this application consist of the feeder rate control gate and the agitator as shown in Figure 2.

An adjustable limestone feed rate control gate was incorporated in this design on the face of the feeder hopper to manually regulate and set the flow of the limestone particles out of the feeder in accordance with stream flow and the RPM of the drum.

The purpose of the agitator is to provide a continuous flow of the limestone particles toward the control gate in the feeder by breaking any arches that may form in the hopper and overload the drive system.

RECIPROCATING LIMESTONE FEEDER

FIGURE 2

1.1.3 Inverted Screw Feeder

Limestone is fed continuously to the rotating drum through a 6-inch diameter hole cut into its feed side where a 6-inch hollow shaft made of schedule 40-pipe is attached to the drum. A 2-inch solid shaft coupled to the hollow shaft extends on the other side to rest on a pillow block to support the rotating drum. A 4-inch diameter hole in the surface of the hollow shaft receives the limestone particles falling through the chute, and the helical fins in the hollow shaft act as an inverted screw feeder to transport the limestones until they fall inside the drum. A casing surrounds the hollow shaft, and it includes a small hopper to funnel the aggregates into the 4-inch hole on the hollow shaft.

1.1.4 Flexible Drive Shaft

In order to provide the necessary feed rate of the aggregate to the drum for various flow rates of the stream the reciprocating feeder must discharge the proper amount of limestone during each operating stroke. A flexible drive shaft supplying power to the reciprocating feeder from the drum shaft was found to be the most suitable possibility for such an arrangement. When the flow rate in the stream is high, the drum turns faster and more aggregates are made available for grinding. The opposite happens when the stream flow is slowed down. This way, after properly adjusting the feed gate on the feeder, the pH level of the stream can be kept constant at any desire value.

For smooth operation of the reciprocating feeder, two speed control units were placed at each end of the flexible shaft. The one attached to the drum shaft increases the input RPM from 35 to 900 at the flexible shaft, and the other having the same velocity reduction ratio delivers 35 RPM to the reciprocating feeder drive shaft. This way torque variations in the shaft are kept at a minimum level when the aggregates in the feeder hopper are jammed, and the agitator is applying pressure to break limestone arches impeding the flow in the hopper.

1.1.5 Rotating Drum

The design of water powered tumbling drums loaded with crushed limestone is critical when hydraulic and grinding efficiencies are considered. The hydraulic efficiency is defined as the ratio of power consumed by the drum to the power supplied by the water in the sluice, and the grinding efficiency is measured by the capacity of drum to deliver the amount of fine limestone particles per unit time, (lbs/hour). The hydraulic efficiency is only a function of the geometry of the drum, and it depends mainly on the water wheel diameter, and drum diameter. The grinding efficiency for an autogenous wet process is more complex and it is mainly affected for a given aggregate material, on the aggregate size, inside drum geometry (diameter, length), drum speed, percent volume of the tumbling aggregate to the volume of the drum, and lift bar configuration. This last item includes number of lift bars, their geometry and their spacing and positioning around the periphery inside the drum.

Some of the experimental work dealing with the above-mentioned parameters will be presented in more detail in the following section of this paper.

For 4 ft^3/sec. of water flow at the pilot treatment station, the final design of the drum included a drum diameter of 36 in., with 44 in. length, and an outside water wheel diameter of 32 in. This drum also contains 22 water wheel blades (vanes) on the outside and 22 lift bars in the inside equally spaced around the circumference of the unit. Life bars made of standard angles,

1½ in. x 1½ in. x ¼ in., are placed along the length of the drum parallel to the axis of rotation, Figure 1.

2. EXPERIMENTAL WORK

To determine the effect of principal parameters on the grinding efficiency of tumbling drum a 12 in. diameter and 8 in. long model was built and powered by a variable speed motor. All tests were run with limestone aggregates in dry condition. It is a generally well known fact that in comminution processes the grinding efficiencies are always higher in wet conditions than the dry ones for similar conditions. However, the relative influence of each parameter as a variable affecting the grinding efficiency remains the same whether the process is wet or dry. It is for this reason that dry grinding was selected in this investigation since it also simplified the laboratory equipment and technique required for the present tests.

Figure 3 shows that for any given aggregate size there is a drum speed at which the grinding efficiency is maximum. For 1½ in. and 2 in. limestone size this was found to be between 65%-75% of the critical speed when the load in the drum occupied 25% of the total volume. The critical speed (Cs) is defined as the minimum speed at which the media in the drum are held against the shell by centrifugal force, i.e., the speed at which the centrifugal force is just balanced by the weight of the media. These values are in agreement with suggested values in the literature for similar cases.

EFFECT OF DRUM SPEED ON GRINDING EFFICIENCY AT 25% OCCUPIED VOLUME

FIGURE 3

The grinding efficiency was found to be maximum for a given aggregate size when the charge in the drum occupied about 25% of the total volume as shown in Figure 4. This can be explained by the fact that there must be enough aggregate mass present in the drum to produce fines but there must also be enough space for particles to collide with minimal impedence from the drum walls. The level of material must be kept as low as possible to prevent larger stones impacts from being cushioned by too high aggregate level. [4]

EFFECT OF VOLUME ON GRINDIND
EFFICIENCY AT 65 % CRITICAL SPEED

FIGURE 4

Figure 5 shows the effect of aggregate size in grinding efficiency. The efficiency is directly proportional to the aggregate size of the tumbling charge in the drum within the limit of this investigation. This is probably due to the fact that increased masses in this case provide additional impact forces which facilitate the breakage process. Once the smaller particles are generated in the charge, the overall available rough surface area in contact in the drum is increased. This increase in the total friction surface in the media results in more fines being produced in the process.

EFFECT OF AGGREGATE SIZE ON GRINDING EFFICIENCY

FIGURE 5

Figures 6 and 7 show the variations of the grinding efficiency with the size and the total number of lift bars in the drum for two different aggregate sizes. The grinding efficiency increases with the number of lift bars (1 in. size) until the spacing between bars reaches a size where particles can lodge there and impede the grinding process. This usually happens when this space is about less than three to four times the aggregate size in the drum.

GRINDING EFFICIENCY WITH 1" LIFT BARS

FIGURE 6

GRINDING EFFICIENCY WITH 2" LIFT BARS

FIGURE 7

The lift bars affect output through two ways; one, by providing a mixing action so that the aggregates will move about and abraise each other, and two, by providing an aid to crushing and chipping, similar to impact action of a continuous anvil. Mixing is important, but if the lift bars are too high and too great in number, stones will be retained excessively between bars and only part of the stones above the bars will be permitted to tumble in a normal cascading fashion in the drum. This can explain the decreasing value of the grinding efficiency in Figure 7 with the increase of the number of bars.

In conclusion it can be said for the lift bars that they serve two purposes, mainly breakage, and mixing of the aggregates. They should protrude above the fines in contact with the drum lining and not confine many stones between their walls. For a given size of aggregate there is a bar height and bar spacing which will produce the maximum grinding efficiency.

As mentioned previously all the tests were done in dry running conditions. Following the completion of the pilot station, similar tests will be performed in actual wet operating conditions in the next phase of this investigation and validity of some of the assumptions will be checked.

A further parameter affecting the grinding efficiency is the amount of water present in the drum during the wet tumbling process. It was, of course, impossible to investigate this parameter within present test conditions. This effect will be studied in in-site testing by varying the number of access holes on the drum shell for water inlet and outlet during the operation of the pilot station.

CONCLUSION

Recent investigations have shown that crushed limestone can be used effectively and most economically to neutralize acidic streams. Water powered tumbling drums loaded with limestone aggregate can make effective use of the energy inherent in the streams and can supply the necessary fines to control the pH level of the water. A self-feeding treatment station requiring very little supervision presents the most economical solution to this problem since it reduces to a minimum level the cost of extensive manual labor otherwise needed in this operation. The main features of such a treatment station consist of a storage bin and hopper, a feeding mechanism which can vary with the flow and acid level requirements of the stream, and some means of metering and transporting the limestone aggregates from the storage unit to the tumbling drum. The solution presented here has the capability of performing all these tasks using only as the sole power source the energy available in the stream. Such a system tested at one pilot treatment station at Otter Creek, West Virginia, was found to be 600 percent more effective than the batch-loaded drum while requiring only one-sixth of its water flow requirements.

The proper design (geometry, configuration and components) of the tumbling drum requires careful considerations. Among them are principally, the rate of flow and acid level of the stream, the aggregate feed rate and size, and the RPM of the drum. Experimental data included in this paper show that the output of fines produced in a drum can be maximized with the selection of proper values of relevant parameters in the final design of a tumbling drum.

NEUTRALIZATION OF ACIDIFIED STREAMS IN WEST VIRGINIA

Peter E. Zurbuch

ABSTRACT

The West Virginia Department of Natural Resources has 25 years of experience in neutralization of acidified streams. Early efforts were on lightly buffered waters that gained most of their acid content from watershed geologic conditions. Research led to a method of treating acid stream flow with limestone aggregate contained in water powered rotating drums (Limestone Drum System). Increased acidification of West Virginia streams by acid precipitation has rekindled research efforts on a problem of larger proportions than that experienced in the late 1950s and 1960s. This paper reviews work on treatment of acidity in natural streams—particularly that dealing with use of the Limestone Drum System. It reports on recent development of a second generation drum that is self-feeding from streamside stored aggregate. The new system's efficiency may permit its application to large streams affected by acid precipitation.

West Virginia has relatively few impounded waters. As a result, fisheries management in the state has focused on stream environments. Many streams in the north central and western parts of the state have been severely impacted by acid mine drainage (AMD). A number of others, especially in the eastern mountains, are lightly buffered and small amounts of acid, from mining or acid precipitation, cause severe problems for fisheries. Mining reclamation and treatment of AMD have greatly improved water quality in the state and good fisheries exist where there had been none for 40 years or more. In the lightly buffered waters, including much of West Virginia's trout habitat, the advent of acid precipitation is reversing these gains. The control of acid production from mining of coal is being offset by increased acid deposition from burning of it.

Peter Zurbuch

THE AUTHOR: Peter E. Zurbuch received a B.S. in forestry from West Virginia University and an M.S. in fisheries from the University of Michigan. He has been employed by the Wildlife Resources Division of the West Virginia Department of Natural Resources since 1956. His initial employment was as a D-J Project Leader for Fisheries Investigations of the Ohio River and its tributary streams. In 1957, he was placed in charge of the states' hatcheries and trout research program. During this period he started research efforts in neutralization of lightly buffered acid streams. He became chief of the Wildlife Resources Division in 1966 and served in that position until 1971. He then moved back into research and has headed wildlife research and special projects working out of the Department's Operation Center in Elkins, West Virginia.

Acid mine drainage that has not been contained by mine reclamation is commonly being treated by the mining industry in the state. Generally, these treatment stations involve the use of hydrated lime ($Ca(OH)_2$) or quicklime (CaO). Recently, some success has been achieved with the combined use of hydrated lime and limestone ($CaCO_3$). AMD neutralization techniques provide valuable information to fishery managers on methods of applying neutralization reagents to acidified waters, problems commonly encountered, and give insight into costs involved. Data cannot, however, be directly applied to lakes and streams being adversely affected by acid precipitation. Significant differences exist. AMD usually has a much higher concentration of solids and flows are small and regulated. Waters impacted by acid precipitation have very low solid concentrations, many near distilled water, and natural flows are large and unregulated. AMD treatment stations are usually near road access, utilities, and a labor force for operation and maintenance. Lakes and streams impacted by acid precipitation are often remote and not readily accessible.

Research on treatment of lightly buffered acid streams was initiated by the West Virginia Department of Natural Resources (DNR) in the late 1950s. The first attempts involved placement of bags of hydrated lime in small tributaries, hoping that a slow dissolution of the material would neutralize acid loads in the main stream. The impracticality of this approach was soon evident, and more sophisticated treatment systems were developed. Four techniques are presented below: hydrated lime/aglime ($CaCO_3$ fines) feeders, streambed limestone, rotary drums, and self-feeding rotary drums.

HYDRATED LIME/AGLIME FEEDERS

Effective stream neutralization requires a slow release of base, ideally with the rate of release regulated by stream flow and acidity. To at least partially fulfill these needs, the DNR initially designed and tested (in the late 1950s) a mechanical feeder powered by stream flow and constructed to dispense calcium hydroxide gradually into the stream. While the original treatment station was crude in construction compared to present

© Copyrighted 1984 :an Fisheries Society.

day systems, the problems encountered then still plague modern counterparts, i.e., the daily maintenance of the feeder to keep the feed free flowing and regulated to stream requirements, and dry storage of large amounts of the reagent.

More recently (1971–1972), the U.S. Forest Service tested a stream powered aglime feeder on Dogway Fork, a tributary of Cranberry River, for about a year. The project experienced many stoppages and neutralization effects varied considerably. The Forest Service concluded the system was not applicable to stream requirements and stopped treatment.

The West Virginia DNR, in cooperation with Trout Unlimited has also experimented with a modification of the mechanical feeder system, feeding aglime or hydrated lime into a mixing vat prior to dispensing into the stream. Power for the feeder and vat agitation is from water piped into the station from an upstream inlet. While effective for a short-term (24-hour) operation, the system has unresolved problems similar to the direct dry feed systems. Because of the numerous inlet and outlet pipes, the system is also subject to freeze up during cold weather.

STREAMBED LIMESTONE

After initial attempts with hydrated lime feeders were nonproductive, much simpler procedures were proposed. Placement of bags of hydrated lime in streams had provided inadequate contact between the base and the water and thus inadequate neutralization. To improve this interaction, limestone aggregate was spread along the streambed. Although effective initially, the benefits of this treatment are often short-lived, as the stone becomes unreactive due to silting and coating with precipitate.

In 1974 a West Virginia chapter of Trout Unlimited treated a small tributary of Dogway Fork of the Cranberry River. Thirty-six tonnes of 2 to 2.5 cm limestone aggregate were spread over a 183 m segment of streambed. At first water quality was improved, raising the stream pH from 4.1 above the stone to a maximum of 6.1 below the treated segment. The reactivity of the stone, however, gradually decreased. Eventually, passage over the limestone aggregate had no significant effect on streamwater pH. Neutralization lasted through the spring and summer months following application. The lowest pH recorded during that period was 5.4.

The full benefits of streambed limestone may not be entirely evident from chemical data alone. In Otter Creek, a stream treated with limestone fines (a waste product from rotary drum operations), residual benefits have continued long after treatment ceased. Native brook trout (*Salvelinus fontinalis*) are now able to inhabit sections of the stream where they were not present before treatment. Size of the aggregate or fines may be important. If stream movement of the bottom material is able to keep a portion of the limestone surfaces reactive, water quality may be improved sufficiently for fish populations to survive.

Similar results have since been noted by a number of researchers (Fraser and Britt 1982). Namely, treatment results in a slight improvement in pH followed by a decline to the original pH. The apparent benefits for fish populations, however, suggest that streambed application of limestone has potential value and should be further researched.

ROTARY DRUM

Problems with coating of limestone aggregate and reduction of the neutralization reaction in streambed applications led to development of the rotary drum system. In order to keep the limestone from coating, agitation of the aggregate in a water-powered rotary drum was proposed as a solution. The first drum was constructed by hatchery personnel using a 151-liter oil drum. The drum was fitted with an axle and house guttering welded to it for water cups so that it would be turned by stream flow. Holes were punched in the drum to permit water to enter and exit. Testing of the drum indicated that, besides keeping the stone from coating, reaction rates were increased as a result of abrasion and production of fine particles of $CaCO_3$ that readily dissolved in the stream flow.

Following this initial success, two manufactured drums were installed in Condon Run (Figure 1), a tributary of Otter Creek, in the Monongahela National Forest near Elkins, West Virginia. These were tested from 1960 to 1962 and showed that the system could be used to treat lightly buffered acid stream flow (Zurbuch 1963).

Figure 1. Condon Run experimental drum station that operated 1960 to 1962.

A federal aid project (Dingell-Johnson) was approved in 1963 to apply the rotary limestone drum system in continuous treatment. Two systems were designed. One, a four-drum station at the head of Otter Creek was intended to neutralize the entire 16 km stream, and to sustain a native brook trout fishery. The second, a four-drum station was installed on a tributary stream of Sherwood Lake, a 67 ha infertile soft-water lake; with the objective to increase productivity of the warm water fishery of the lake.

The Sherwood Lake installation was operated from 1964 through 1969 and its effects were reported by Sumner (1970). While there was an overall increase in the standing crop of fish, it could not be directly attributed to treatment. The lake was changed from a very soft water lake (0–400 μeg/L alkalinity) to a soft water lake (420–800 μeg/L alkalinity). It also shifted from a slightly acidic environment (mean pH 6.6) to a slightly alkaline one (mean pH 7.1). Dissolved calcium remained low during the first two years of treatment, never exceeding 80 μeg/L. In the third year (1967) the concentration reached 140 μeg/L. In 1968, the fourth year of treatment, there was a dramatic increase in calcium concentrations, with levels ranging from 180 to 340 μeg/L. Sumner (1970) postulated that much of the $CaCO_3$ initially dissolved into the lake water was absorbed in the mud of the lake bottom. Further, once the mud was neutralized the chemistry of the lake water improved, and if treatment were continued even more significant

increases in dissolved calcium, alkalinity, and pH would have been achieved.

The drum installation was within 1 km of the lake and stream dissolution of the limestone was probably not complete by the time it reached the lake. Within the stream, pH was normally raised two full units above vs. below the treatment, from 6.6 to 8.6, and total alkalinity from 136 μeg/L to 300 μeg/L.

The Otter Creek installation (Figure 2) was operated for 15 years from 1964 to 1979. Research results for the period 1964–1968 have been reported by Menendez (1974). A native brook trout population was established for about half of the length of the treated stream. The population was still expanding when the last survey was made in 1970. Subsequent to this the area below the treatment station was designated a wilderness area, thus, limiting additional fish surveys. The annual neutralization of acid load was in excess of 83% at the treatment site. Downstream, at the stream mouth the reduction varied from 33% to 50%. Alkalinity immediately below treatment increased from a pretreatment of 60 μeg/L to around 200 μeg/L. Alkalinities at the stream mouth were increased by only 20 to 40 μeg/L. The pH values below the drum site were usually kept above 6.0 and reached a high of 7.3. In the lower stream, effects on pH were not as discernible.

Construction of the Otter Creek station cost $17,761 and the Sherwood Lake station $13,479 (1963 dollars). For the period 1964–1969 the Otter Creek station required an average 60 man-days per year for maintenance and operation and 53.2 tonnes of limestone aggregate per year. The Sherwood Lake station required 42.4 man-days annually and averaged 44.8 tonnes of limestone consumption per year. Maintenance and operation included stockpiling of limestone, hand-loading the drums, and maintenance of the drums, sluice, dam, and grounds. It was felt that the drums operated satisfactorily and at a reasonable cost. Very few mechanical problems were encountered.

Beaver (*Castor canadensis*) control on treated streams is an important consideration. Considerable effort was spent at both sites to keep beaver cuttings out of the sluice area. At Sherwood Lake the entire dam area was eventually fenced, while live trapping and removal alleviated the problem at Otter Creek.

Extremely cold weather did not freeze up the drums if there was sufficient operating flow. If flows decreased below operational levels (0.014 m^3/s), and the drums froze, stopping rotation, they would resume operation within a few hours of increased stream flow. It was not uncommon to break an 8 to 15 cm cacoon of ice surrounding an operating drum to permit loading it with stone. Otter Creek winter temperatures were frequently −10°C or below, with a low recorded at −28°C.

A coal company attempted to use the drum system to neutralize a stream draining a large strip mining operation. They installed a treatment station on Beaver Creek, a tributary of the Blackwater River near Davis, West Virginia. The acid load requiring neutralization, however, was more than the capability of the drums, and neutralization was only about 20% effective. During one sampling period, stream flow was 0.03 m^3/s and pH above the treatment station was 4.0 with a total acidity of 1760 μeg/L. Immediately below the drums, acidity was reduced to 1500 μeg/L; and to 1440 μeg/L 3 km downstream at the mouth of the stream. The pH remained at 4.0 at both

Figure 2. Otter Creek four-drum continuous neutralization station that operated 1964 to 1979. See cover photo.

downstream sites. The treatment station was operated sporadically for a few years and then abandoned.

The U.S. Forest Service installed a one-drum treatment on Bear Run, a tributary of the North Fork of Cherry River near Richwood, West Virginia. The stream is polluted with AMD and the drum successfully neutralized enough acid to permit trout stocking in the headwaters of the North Fork. Data are available for years 1970 to 1973. Stream flow fluctuated between 0.014 m^3/s and 0.034 m^3/s and the drum was refilled every two weeks. The pH of the untreated water ranged from 4.0 to 5.5 and conductivity from 52 to 110 μmhos/cm. At the mouth of the stream, about 1 km downstream from treatment, the pH was raised 1.0 to 1.5 units.

The Pennsylvania Department of Environmental Resources (PADER) recently released a comprehensive report evaluating techniques that use limestone in neutralization of AMD (PA DER 1982). Static barriers, downflow beds, upflow beds, alternating flow beds, an autogenous cleaning mill, and rotary drums were evaluated. The report concluded that crushed limestone is a feasible alternative to lime or other base treatments for treating AMD. Further, they recommended use of the rotary drums for final treatment of effluent that is pretreated using a filter bed of limestone having backwashing cleansing capabilities. The pretreatment bed's purpose is to remove metals (Al, Fe). The report is an excellent reference for fishery scientists studying use of limestone to neutralize acidified streams.

SELF-FEEDING ROTARY DRUM

In the mid-1970s the DNR became aware of the impact of acid precipitation on some of the major trout streams of the state. Streams that had once been stocked with trout from January through June were now unable to accept fish until late April or early May because of low pH. A study was made of the feasibility of treating these streams using the rotary drum system developed at Otter Creek. Hand-loaded drums, as used at Otter Creek, however, were impractical. For example, it was estimated that over 70 drums would be required to handle flows and acid loads for Cranberry River—formerly one of the premier trout streams in West Virginia.

During the original development of the Otter Creek drums it was apparent that at small drum loads, 25% or less of drum volume, the limestone reaction rate was much higher. It was believed that if a drum could be developed that maintained a light load, and fed itself from a storage bin, a more efficient treatment system was possible. To test this hypothesis, the Otter Creek station was repaired in 1980 so that one drum could be put into operation. It was hand-loaded at 0.5 hour intervals in order to maintain a 91 kg to 114 kg load of stone. These tests indicated that it might be possible to increase the drum output by 600% if a self-feeding drum could be designed and successfully tested.

A cooperative project was entered into in 1981 between the DNR and the College of Engineering at West Virginia University (WVU) to design and construct a self-feeding rotary drum and attendant storage bin. Design goals were: (1) development of a self-feeding drum powered by stream flow; (2) production of up to 54 kg/h of limestone fines (90% with 38 μm diameter or less) at an operating flow of 0.113 m^3/s; (3) unattended operation with minimum maintenance; and (4) bin storage of a week's supply of stone (9.1 tonnes). The Otter Creek station was repaired, a new sluice installed, and a self-feeding drum station placed into operation in March 1983 (Figures 3 and 4).

Figure 3. Experimental self-feeding rotary drum limestone neutralization station installed at Otter Creek in 1983. Photo shows sluice and sluice gate; building enclosing drum apparatus, storage bin, and limestone stockpile.

Figure 4. Self-feeding limestone drum apparatus. Photo shows water powered drum, drum feed, flexible drive shaft, reciprocal feeder and bottom of 9.1 tonne bin.

In preliminary testing (March–May 1983) the self-feeding drum performed well. In excess of 36 tonnes of 3.8 cm limestone were consumed during testing. The system operated continuously for three weeks during one test period without mechanical problems or feed stoppages. In one previous 24-hour test, the self-feeding drum produced fines at a rate of 57 kg/h into a stream flow of 0.184 m^3/s. Above treatment the pH was 4.7, total acidity 108 μeg/L, and alkalinity 30 μeg/L. After treatment, and downstream 0.4 km, pH was raised to 8.4, alkalinity to 680 μeg/L and the acid load completely neutralized. The self-feeding drum design and its mechanical operation are presented in more detail in Gencsoy et al. (1982).

Laboratory research indicates that an even more efficient drum may be possible with variations in drum design and stone size. At the present output, the system can produce six times the neutralization of the hand-loaded drum (54.4 kg/h vs. 9.1 kg/h at an operating flow of 0.113 m^3/s). The feeder can be adjusted to produce any desired treatment rate lower than the maximum rate. The design of a neutralization station would be similar to the hand-loaded drums. A series of self-feeding

drums would be powered by the stream flow channeled over the drums by a common sluice. As flow increased or decreased, more or fewer drums would be automatically placed in operation. A necessary addition to the new installation is a storage building to keep limestone dry during winter operation. A new system will be tested this fall, winter, and spring, and a report is expected next summer (1984).

As reported by Zurbuch (1963), fines that are not dissolved provide additional buffering action when drum treatment is stopped. Four days after treatment had stopped, following a 30-hour test, residual limestone fines were still neutralizing about 37% of the acid load. Six days after treatment 25% was being neutralized. One of the questions that will be investigated in future studies is how $CaCO_3$ fines that build up in the streambed compliment the fines dissolved in the flow during neutralization.

Construction costs of an eight-drum treatment station were originally estimated at $250,000 (Zurbuch 1981). Otter Creek construction of the three-drum station shows this estimate to have been fairly close. The present estimated cost of a three-drum installation is $150,000. Prorating the costs per drum would amount to about $50,000 each. Such a station should efficiently operate on flows from 0.028 m^3/s to 0.34 m^3/s. Maximum station production of $CaCO_3$ fines at the higher flow would be 163.2 kg/h or 3.92 tonnes/d.

The costs of construction of rotary drum facilities can be roughly compared to those for aglime and hydrated lime silos. The PADER estimates today's cost of a 27.2 tonne capacity hydrated lime silo to be $84,000 with treatment capability of up to 0.242 m^3/s of flow and feed rates of 9.4 kg/h to 45 kg/h. Sweden (Fraser and Britt 1982) reports that a silo that adds 200 tonnes of aglime annually to a treated stream costs $20,000 (1981 dollars). The annual application converts to an average rate of 22.8 kg/h. One self-feeding rotary drum should produce 54 kg/h of $CaCO_3$ fines into a flow of 0.113 m^3/s. Thus, one drum appears equivalent to two Swedish silos in application rate, and station construction costs would be about the same ($50,000 vs. $40,000). Two of the drums are equivalent to one Pennsylvania silo in flow capacity, and construction costs are again about the same ($100,000 vs. $84,000). The two drums would have the capacity to more than double the maximum output of the Pennsylvania silo—108 kg $CaCO_3$ fines/h vs. 45 kg $Ca(OH)_2$/h. Savings in operation costs by using the rotary drums could result from reduced labor, better neutralization efficiency of drum $CaCO_3$ fines to aglime, and the lower cost of limestone aggregate relative to both aglime and hydrated lime. It is stressed that the above calculations are rough and preliminary. Firm data will be available when testing is completed at the Otter Creek station and a final report prepared.

RELATED STUDIES

While the emphasis of this report is on stream neutralization, there have been two long-term lake liming projects in West Virginia. Spruce Knob Lake is a 10.5 ha impoundment located near the highest elevation in the state (1,483 m). The impoundment was opened to fishing in 1953. In 1958 fish kills occurred that were related to acidification with pH readings of 5.2 to 5.6. In April of 1958, 9.1 tonnes of agricultural limestone ($CaCO_3$-aglime) were applied by boat to the lake. The pH was raised to a range of 6.0 to 6.8. In October 1958 the watershed was treated with 95.3 tonnes of aglime. The watershed was similarly treated in 1971 with 30.8 tonnes and in 1978 with 61.7 tonnes. Generally, the pH of the lake has stayed above 6.0 since the initial treatment. There has been no additional reported mortality of rainbow trout (*Salmo gairdneri*) or other species related to acid water during this period. Studies have not been made to determine the cause of the acidification of the lake, nor have there been any in-depth chemical analyses of the effect of the neutralization treatments.

The other treated impoundment is Summit Lake, a 17.4 ha impoundment, located some 90 km southwest of Spruce Knob Lake, but still in the mountainous area of West Virginia. The impoundment has had acid water problems since its construction in 1956. Aglime has been used to neutralize the acid with amounts ranging from 1.4 tonnes in 1965 to 9.1 tonnes in 1958. For the last 10 years 0.3 tonne of hydrated lime ($Ca(OH)_2$) has been applied annually together with 4.5 tonnes of aglime. The lake pH is usually less than 6.0 before treatment and has been as low as 5.2. Following treatment in March or April, pH ranges from 6.0 to 6.8. On several occasions fish kills have occurred following treatment. Species involved have included stocked rainbow trout and resident smallmouth bass (*Micropterus dolomieui*) and green sunfish (*Lepomis cyanellus*). While some investigations have been made to determine the cause of these kills, no definitive answers have been obtained. In 1973 the lake was drained for repair and 91 tonnes of aglime were spread on the lake bottom. This apparently had little lasting effect on water quality as the lake required treatment the following spring.

Other related studies involve measurements of water quality and precipitation chemistry for streams in West Virginia potentially sensitive to acid deposition. Flow and stream chemistry data have been collected weekly since 1981 in Otter Creek at a station above the treatment site. Relative to similar data collected in 1964 through 1968, average annual values for pH and free acidity have not changed significantly over time. Using only measurements for winter months (January–March), however, free acidity has increased significantly from a mean of 6.3 μeq/L in 1964–1968 to 15.6 μeq/L in 1981–1982 (Table 1). Bedrock geology appears to be responsible for much of the free acidity in Otter Creek, but cannot account for the increase in H^+ since 1964–1968.

Table 1. Change in free acidity levels in Otter Creek during winter months (Jan–Mar) over the period 1964 to 1982.

Year	Free acidity* (μeq/L)	
1964	6.2	
1965	6.5	*Periods*
1966	6.5	1964 to 1968 $\bar{x}$ = 6.3
1967	7.2	1981 to 1982 $\bar{x}$ = 15.6
1968	7.3	
1981	11.4	
1982	12.2	

* Free acidity is estimated from ambient pH. The mean free acidities for the winter months from 1964 to 1982 are based on regression analysis (r^2 = 0.36 and p = <0.05), while the period means are calculated from weekly data.

Similar flow and chemistry data are collected biweekly at eight stations in Cranberry River (pH 5.6 to 5.8 at the mouth). These data in conjunction with long-term daily flow records collected by the U.S. Geological Service are being used to develop a computer model to determine if self-feeding rotary drum stations, installed in the headwaters of the Cranberry, could add enough alkaline material to permit a trout fishery to exist downstream 48 km to the river mouth. The first run of the simulation model indicated that two six-drum stations could neutralize enough of the acid to provide suitable water quality even with worse case conditions—the wettest year and highest daily flow. An estimated 1,800 tonnes of limestone would be consumed at each station over each year. The model is still in development and the above conclusions are tentative.

In 1983 a survey of streams in West Virginia potentially impacted by acid deposition was initiated. Some 90 streams have been selected to be sampled twice a year—spring and fall. Data will be used to categorize streams based on buffering capacity, effects of acid deposition, and watershed geology and soils. This study should give us information on water quality trends and a good appraisal of the effect acid deposition is having on the fisheries of West Virginia.

PERFORMANCE REPORT

STATE: West Virginia PROJECT NUMBER: F-24-R-3

PROJECT TITLE: Acid Water Studies

PERIOD COVERED: March 1, 1983 through June 30, 1984

Study Objective: To (1) gather background data on two acid impacted trout streams to determine feasibility of neutralizing acidity; (2) test a self-feeding limestone drum; and (3) survey acid impacted streams in West Virginia.

(1) Job Number and Title: I-2 Testing Second Generation Limestone Drums

Job Objective: To field test a proto-type self-feeding limestone drum, and determine the feasibility of constructing acid treatment stations on the Cranberry River.

(a) Activity: A self-feeding drum system, attendant water sluice and limestone storage building, were installed at the site of the old Otter Creek treatment station. Three drums were tested during the project segment. One drum was a modified model of the original hand-loaded one and the others newly designed ones. Tests were conducted through a range of flows, climate conditions and drum design modifications.

Some 300 tons of limestone aggregate of uniform size and quality were obtained for test purposes. Efficiency of the treatment was based on continuous operation, automatic adjustment to flow change, minimal maintenance, and production rate of fines dissolving into the stream flow. The latter was measured by feed/use rate of stone in pounds per hour. Water chemistry and measurement of $CaCO_3$ dissolution were taken at sample sites below the treatment station.

(b) Target date for achievement: June 30, 1988

(c) Status of progress: On schedule

(d) Significant deviations: None

(e) Recommendations:

It is recommended that testing continue on the self-feeding drum through the next fall, winter and spring. Testing will concentrate on the optimizing of the drum production of limestone fines (use rate). When this has been achieved, various size screening will be installed in the drum to determine effect on drum output and downstream chemistry. Following these tests the drum will be operated continuously over the winter and spring months. Effects on downstream chemistry and limestone fines sedimentation will be studied weekly during continuous operation. Finally, in the late spring (1985), other types of limestone will be tested. These will vary in hardness and chemical constituents. Effects will be measured on drum output and changes in stream chemistry.

It is anticipated that a final report will be prepared early next summer. This report will cover effectiveness of the treatment system, and economic

advantages when compared to other treatment methods. Data will be analysed in conjunction with those gathered in Job 1 to determine if the method can be applied to the Cranberry River.

(f) Cost:

Total	State	Federal
$10,000	$2,500	$7,500

(g) Remarks:

General

A history of the limestone drum treatment system leading to the present work is appended (Zurbuch 1984). The design of the self-feeding system has been reported by Gencsoy et al (1982) and is also appended.

Drums Tested

Three drums were tested during this segment. The B model is a modified drum from the original hand-loaded drums (A model) used to treat Otter Creek from 1964 to 1979. Model C is based on specifications derived in a research contract with the College of Engineering, West Virginia University (WVU). Model D is a recently constructed drum of the same design as Model C, but of lighter materials to reduce its weight by some 1,000 pounds. Very little testing of this drum was accomplished during this segment.

Major design characteristics of each drum are:

Model B—Fifty-inch diameter overall with 34-inch inside drum diameter, 18 water vanes (cups), empty weight 790 pounds (without feed cylinder attached).

Model C—Fifty-two inch diameter overall with 36-inch inside drum diameter, 22 water vanes (cups), empty weight 2,100 pounds (without feed cylinder attached).

Model D—Same design as Model C, but constructed of lighter materials, empty weight 1,010 pounds (without feed cylinder attached).

During testing various internal drum configurations were used. These involved number of lift bars, size and shape of lift bars, number, size and shape of water holes, and various types of hole screening.

Limestone Used

Care was taken to use the same size and quality limestone aggregate throughout the tests. Stone was obtained from the Germany Valley, West Virginia quarry. The quarry operators stockpiled a special lot of the desired size stone that was mined from the same quarry site. Three random samples, taken from the quarry stockpile, of stone were analysed for hardness and chemical content (Table 1).

The size of the stone used was AASHO Number 57. The percentages by weight passing square openings of this size stone are: 1.5-inch 100%, 1-inch 95-100%, 0.5-inch 25-60%, smaller openings 0-10%.

Table 1. Germany Valley, West Virginia, high calcium limestone used in 1983-84 Otter Creek testing.

	Sample 1	2	3
Chemical Composition % Weight			
Calcium Carbonate $CaCO_3$	95.22	94.32	96.72
Magnesium Carbonate $MgCO_3$	0.29	0.29	0.59
Silica SiO_2	1.16	1.17	0.87
Aluminum Oxide Al_2O_3	0.06	0.06	0.06
Iron Oxide Fe_2O_2	0.11	0.11	0.11
L. A. Abrasion %	34.16	34.06	33.82

Sluice Opening

Tests were made to compare two type sluice openings to direct water onto the drums. One was a vertical sided slot and the other an angled slot (Figure 1). The angled slot directed flow into the drum vanes at approximately vane-angle after passing the top midline of the rotation. The devices were constructed to permit changing their position relative to the horizontal position over the drum. Model B and Model C drums were used to evaluate the two type slots.

Figure 1. Sluice water openings tested.

All tests shown in Table 2 were run with same weight of stone (400 lbs) and same flow (5.0 cfs). Location of the slot refers to the most efficient location of the rear (upstream) edge of the slot opening in inches downstream from the vertical center line of the drum.

Table 2. Comparison of efficiency of water power of a vertical slot opening to an angled slot opening in operation of two limestone drum models.

	Vertical slot		Angled slot	
Drum model	max. rpm	location	max. rpm	location
B	23.0	8.0 in.	15.0	0.0 in.
C	18.5	10.0 in.	15.5	5.0 in.

There did not appear to be any change in drum rpm by changing the closeness of the drum to the bottom of the sluice between one and three inches. Experiments by the Pennsylvania Department of Environmental Resources (PA DER) (1982) indicated a significant increase in hydraulic efficiency with a drum using a one-inch water drop to a drum with a six-inch water drop. Additional testing will be conducted at Otter Creek to confirm the data above.

In summary, testing indicated a vertical slot design to be the most efficient method of directing water power to the rotating drums. This design was used in constructing an adjustable opening slot. This adjustable slot will be important in calibrating correct flows to a series of drums and to shut off flow to an individual drum for repair and maintenance.

Water Jet

The reciprocal feeder delivers a small amount of limestone dust and fines along with the coarse aggregate to the feeder cone. After a few days operation this material will cake in the inverted screw feeder cylinder and not permit stone to enter it. Stone continues to drop from the reciprocal feeder and, not being able to enter the cone, piles up on the floor on each side of it. To over-come the caking, a small jet of water was introduced into the cone that effectively kept it clean (Figure 2). The water is taken from the side of the sluice upstream from the drum. A one-inch hose conducts the water by gravity flow to a pipe welded to the inside of the feed cone. The water jet operated throughout the test period when protected from sub-zero freezing (discussed later). During summer flows, the perforated plate covering the water takeoff on the side of the sluice must be brushed weekly to remove alage accumulation. The water jet provides an effective and economical means of preventing caking of limestone fines and dust in the inverted screw feeder.

Figure 2. Water jet and feed cone adjustable liners.

Feed Cone Liners

The inverted screw feed cylinder turns inside the feed cone assembly. Stone drops into the cone and is held there until the access hole to the screw feed rotates to the up-vertical position permitting the stone to drop inside. In the manufacturing process there is an allowable space of one-fourth inch between the outer circumference of the screw feed and the inner circumference of the feed cone assembly. This permits small pieces of aggregate chips (one-eighth inch or less in diameter) to be pulled by the rotation of the screw cylinder in between these two surfaces. These stone pieces produce a braking resistance and reduce the hydraulic efficiency of the drum.

To overcome this problem adjustable metal liners were placed on the inside of the cone on three of its four sides (Figure 2). The upstream side does not need one since rotation of the cylinder does not let aggregate enter the space between the two surfaces. The liners are adjusted as close as possible to the rotating feed cylinder. This system keeps the small aggregate chips from getting between the two surfaces and holds them in the cone until they are washed into the inverted screw cylinder. The front and rear liners are made of one-eighth inch thick carbon or low alloy steel. The downstream liner must be made of one-fourth inch thick stainless steel. This is because occasionally a piece of aggregate will be crunched between the edge of the liner and the rotating rear edge of the access hole of the screw cylinder.

Screw Cylinder Modification

Another way small aggregate chips entered the space between the cone assembly and the screw cylinder was by dropping out of the cylinder when the access hole was in the full down position. This was overcome by modification of the interior of the screw cylinder (Figure 3). A slanting plate was placed under the access hole to carry stone and stone particles beyond the hole with assistance from the water jet. An inner rim to the access hole was constructed to keep stone particles from rolling out of the hole when it rotated to the full down position.

Figure 3. Modified inverted screw feed cylinder.

Modifications of the screw cylinder and liners for the cone assembly solved a major design problem and were incorporated in blueprints and specifications of the treatment system. These modifications, along with the washing action of the water jet, kept the feed cylinder running smoothly and overcame the breaking problems from small aggregate chips getting between the surfaces of the cone assembly and the feed cylinder. It is important that in the construction specifications the maximum allowable eccentricity of the inverted screw feed cylinder be one-eighth inch or less. If it is more than one-eighth inch the usefullness of the adjustable cone liners is reduced.

Reciprocal Feeder Agitator

The original design of the reciprocal feeder agitator did not keep the stone from bridging in the hopper and stopping delivery to the drum. A number of designs were tested that led to the present one (Figure 4). This design keeps the stone free flowing and some 200 tons of stone have been fed through the feeder without stoppages due to its operation.

Figure 4. Agitator for reciprocal feeder.

The agitator receives considerable stress from crunching of stone within the hopper. To withstand this stress it is made from one-fourth inch thick stainless steel. The welding of the vertical section to the attachment plate must be carefully done to specifications. If this weld is weak, the vertical section can break loose and fall into the feed cone. Because of this possibility, a safety wire should be attached to the vertical section of the agitator to keep it from entering the cone assembly should it break loose. This will prevent damage to the inverted screw feed cylinder.

Drum Adjustment to Flow Changes

To understand the operation of the self-feeding drum, some terms need defining. The drum uses "autogenous" grinding which is a grinding process using the aggregate itself for abrasion. The "feed rate" is the input into the drum of the aggregate expressed in pounds per hour. The "use rate" is the output of the drum of fines from the grinding process in pounds per hour. A "stabilized" drum is when the "use rate" equals the "feed rate" and the turning speed of the drum in rpm remains constant for a given operating flow. The feed rate is a function of the rpm of the drum imparted to the reciprocal feeder and the gate setting on the feeder. Stabilization of the drum occurs when the combination of amount of stone in the drum and its rpm produces a grinding efficiency or "use rate" equal to the feed rate. Before this point is reached the drum is either: (1) increasing its loading with slowing rpm as grinding efficiency improves and feed rate slows; (2) decreasing its loading with accelerating rpm as grinding efficiency declines and feed rate increases; or (3) "overloading" because the drum's load has exceeded the point of additional grinding efficiency with additional load and the feed rate is more than the use rate. Overloading is the result of opening the reciprocal feeder gate too far so that more stone is delivered for each revolution than the drum is capable of grinding in a stabilized state.

"Critical speed" is when the rpm of the drum is high enough to hold the stone load to the outer surface by centrifugal force. At this speed there is very little grinding action. With the drums tested this speed was 42 rpm. When the self-feeding drum is started empty it will not start grinding action until enough stone is fed into it so that rpm are decreased to the critical speed or below.

Examples of the drum stabilization process are shown in Figures 5 and 6. In these examples, if the operating flow of 4 cfs of a stabilized drum were reduced to 3 cfs, the drum's rpm would be reduced from 30 to 25. This would be because the drum load of 300 pounds would stay the same initially, and with less water power (3 cfs), the rotation would be slower. The use rate, however, is higher than the feed rate (84 vs 70 lbs/hr), thus, the drum will lighten until it reaches 240 lbs, stabilizes at 27 rpm, and the feed and use rates are the same at 96 lbs/hr.

In actual stream operation, the changes in operating flows are gradual and, thus, the changes in drum rpm (and corresponding feed/use rates) are not as noticeable as in the example given. The process described permits individual drums to adjust to changes in operating flow. When the first drum in a series approaches its maximum output, the second drum starts operating as excess flow passes over the first drum's sluice opening. Thus, the treatment stations ability to adjust treatment to changes in stream flow is the result of both the individual drum's ability to adjust to changes in its operating flow and the changing of more or fewer drums in operation based on more or less sluice (stream) flow.

Figures 5 and 6. Examples of drum stabilization at operating flows of 4 cfs and 3 cfs.

10-Ton Storage Bin

Under a contract with the DNR, The College of Engineering at West Virginia University designed the 10-ton bin and the feeder system (Clites 1982). Engineers at WVU were concerned that the 10-ton storage bin and/or the reciprocal feeder hopper were potentially problem areas that could cause stone bridging and stop the free flow of aggregate to the reciprocal feeder. The bin and hopper (Figure 7) did not bridge once in over an 18-month test period and with some 300 tons of stone passing through them. The stone flowed freely in all cases; whether it was loaded dry, wet or with frozen clumps of aggregate. The wet or frozen stone did cause problems of bridging in the area of the agitator of the feeder and this will be discussed later.

Figure 7. Self-feeding water powered limestone drum acid water neutralization system.

Stone Storage and Handling

As was experienced in previous testing, stone should be loaded into the bins in a dry condition. A portion of the station's yearly stockpile needs to be stored in a building enclosing the bins. This is the amount estimated that would be used by the treatment station during the period of extreme winter conditions. In West Virginia this would be a four-month period from November through February. Before or after this period, weather conditions are such that stone can periodically be replenished in building storage from that stored outside. In treatment of the Cranberry River, it is estimated that a year of maximum treatment would require use of 1,700 tons at each of two six-drum stations. About one-half of this would be stored inside and one-half outside. The storage building must be designed then to have an area large enough to store the amount necessary. This storage area is dependent on how high the stone can be piled using the end loader that is also used to load the 10-ton bins.

At Otter Creek stone was stockpiled to an average height of five feet. An area of 900 square feet was able to accommodate 160 tons of stone. This would supply one drum for four months of operation running at a maximum output of 120 pounds per hour or 10 tons per week. A six-drum station would require 5,400 square feet of storage area for 960 tons of aggregate. Figure 8 shows the relationship between the Otter Creek storage building and that proposed for a six-drum station on the Cranberry River.

Figure 8. Relationship of stone storage of the Otter Creek station to proposed Cranberry River station.

Movement of stone from outside storage and in bin loading is important in economy of time and effort. A John Deere JD24-A end loader was used at Otter Creek for movement of stone and loading the 10-ton bin. This loader is a small wheeled vehicle with a 0.39 cubic yard bucket. The bucket's average load of stone was 800 pounds (0.4 ton). An operator could easily pick up a load from inside storage, move it to the 10-ton bin, and return to the stockpile in one minute. To completely fill an empty 10-ton bin required 25 minutes. In a six-drum station, to completely fill six empty bins would require 2.5 hours. In once-a-week servicing of the station, a crew would have ample time for travel, replenishing stone in bins and other maintenance in a normal 8-hour work day.

Movement of stone from outside storage to inside storage averaged two minutes per round trip. Moving 960 tons (a four-month supply for a six-drum station) would require 80 hours or 16 days (five hours moving stone, one hour maintenance, and two hours travel each day). This may be excessive. The movement time could be reduced to one week by using a larger loader with a 1.25 cubic yard bucket. This will be studied further. It may be best to have a small loader at each station for loading bins and a larger loader, transportable between stations, for moving stone from outside to inside storage. The larger loader could substitute for a smaller one if it were inoperative. If the larger loader could pile stone higher in the storage building, the size of the building may be reduced.

Winter Operation

Successful winter operation of the treatment station was one of the major objectives in this project segment. Addition of the water jet in the feed cone, previously discussed (Figure 2), required modification of the treatment station to include a small, heavily insulated, heated room around the feed mechanism as shown in Figure 7. This was required when testing showed the hose to the jet would freeze solid at temperatures below 0° F. Temperatures experienced at the station are given in Figure 9 for the middle of December 1983 through the first

Figure 9. Maximum/minimum outside air temperature and feeder room temperature at the Otter Creek station, December 1983 through February 1984.

of February 1984. The room was kept as small as possible to conserve fuel and still provide sufficient work space. It was heated using a 30,000 BTU LP gas stove. The stove had a thermostat and could be adjusted for any desired room temperature. A 1,000 gallon capacity LP gas tank was positioned outside the storage building. The heated feeder room eliminated all freezing problems with the water jet. It was also found that heat from the room was funneled up through the 10-ton bin. Stone that was placed in the bin wet or frozen was dried out by this heat. The heated room could be kept in the 60-70° F. range for operation of the feed mechanism. If wet stone were placed in the storage bins, the heat could be increased to 80-90° F. to dry the stone. In one case, frozen clumps of stone were placed in the bin and the heat increased in the feeder room. The clumps were thawed and the wet stone dried in three days.

Using the heated feeder room, it is felt that the treatment system can be kept working at below 0° F. outside air temperatures without any problems. Operation of the station requires sufficient flow to power the drums. At very low temperatures the Otter Creek's water sources become frozen and stream flow can be reduced below that necessary for drum operation. Within a few hours of thaw conditions, the sluice flow increases, the drum(s) thaw loose and start operating again.

Storage Building Design

The Otter Creek storage building was built enclosing the sluice and drums as shown in Figure 10. The building is of the pole design using metal and Fiberglass sheathing. During cold periods the water from the sluice and drum operation produced moisture that condensed on the inside of the storage building.

Figure 10. Otter Creek experimental treatment station.

This would drip on the stone loaded in the 10-ton bin and stored on the floor. To overcome this, a roof was constructed over the sluice and drum ramp separating this area from the rest of the building (Figure 10). This effectively eliminated the problem.

In future storage building designs the sluice and drum ramp will be placed outside the building as shown in Figure 11. Besides eliminating moisture condensation, the size of the building will be reduced.

Figure 11. Proposed change in treatment station building design.

Comparison of Models B, C and D Drums

Under a contract with the DNR, the College of Engineering at WVU designed a self-feeding rotary drum system. The drum itself was designed using data collected in lab tests at the University (Pappajohn 1983), from that gained in use of the hand-loaded drums at Otter Creek (Zurbuch 1963), and from an analysis of drum design by Pearson and McDonnell 1978.

In the initial testing of the new drum (Model C) its performance did not meet expectations. In fact, its efficiency for grinding was less than that experienced with the modified hand-loaded drum (Model B). Because of this, much of the project segment was used in comparison testing of the two drums and trying to duplicate dry grinding lab data with wet grinding under actual stream treatment conditions. Results of this testing are summarized as follows:

A. Effect of Drum Weight—The new drum (Model C—2,100 lbs) was constructed of much heavier materials and, thus, weighed considerably more than the older drum (Model B—790 lbs). It was slightly larger in diameter, 36 inches vs 34 inches for Model B, with an overall diameter of 52 inches vs 50 inches. Model C contains 22 water cups while Model B has 18. Model C had 22 lift bars while Model B had 9. The additional number of lift bars and water cups should have increased Model C's grinding efficiency. It was felt that drum weight may be a significant factor and the reason for the poor performance of the new drum. To test this, both models were run in identical tests to measure maximum rpm through a range of flows with the drums empty and with the same stone loading.

The recently acquired Model D drum was run through the same tests. This model is the same design as Model C, but constructed of lighter material with a weight of 1,010 pounds. Figure 12 shows the results of the tests and indicates drum weight is a significant factor in determining the maximum rpm obtained at various operating flows. Another analysis was made comparing operating loads and rpm of Models B and C at 4 and 5 cfs flow. These data, Figure 13, further substantiate that a lighter drum is more efficient than a heavier one.

Figure 12. Hydraulic efficiency of light weight drums (Models B and D) to heavy drum (Model C).

Figure 13. Drum loads of Models B and C and resulting rpm at flows of 4 and 5 cfs.

The heavier drum probably increases friction resistance in the pillow block bearings causing it to turn slower and carry less stone than the lighter drum. Both the slower rpm and smaller stone load would decrease the drum's grinding efficiency. Indication of the effect of bearing friction was shown during greasing of the bearings. In one instance the rpm of an operating drum was increased from 22 to 24 rpm by greasing the outer bearing. To provide constant greasing, automatic greasers were added to the pillow blocks.

B. Effect of Number of Lift Bars—WVU lab data indicated addition of lift bars would increase grinding efficiency of a drum. Modifications of the number of lift bars in both models showed this to be true (Figure 14). All tests were conducted at the same reciprocal feeder gate opening (4.0 cm). Test drums were run overnight at each flow to permit stabilization of the grinding rate. The curve labeled C 22/11 refers to the Model C drum with 22 lift bars, 11 of which have water access holes. The point labeled C 11/11 is the Model C drum in which 11 of the lift bars were removed. Reduced grinding efficiency caused it to overload with stone at the maximum (5 cfs) operating flow. The curve labeled B 9/9 refers to the Model B drum containing 9 lift bars, each with water access holes. This drum's performance shows the greater efficiency of the lighter drum. When the number of lift bars were doubled, curve labeled B 18/9, efficiency was substantially improved.

The question remains of how efficient the Model D drum will be with weight reduced some 1,000 pounds from Model C's weight. These tests will be conducted in the next project segment.

Figure 14. Stabilized use rate of Model B and Model C drums at various flows and configurations (reciprocal feeder gate opening of 4.0 cm).

C. Effect of Area of Water Access Holes—The amount of area for water to enter and leave the drum is dependent on number of holes, size of holes, size of screening covering holes, and occlusion of holes by stones and stone fines. The effect of varying hole area is difficult to measure due to variables associated with the grinding process. Figure 14 shows that in short periods of operation (12-24 hours), addition of more water access area improved performance of both Model B and Model C drums. Model C drum performance (curve C 22/11), substantially improved when all of the lift bars contained access holes (curve C 22/22). Some additional efficiency was obtained when the holes were increased in size from 7/16-inch diameter to 5/8-inch diameter as shown by the curve C 22/22^{+}. Model B shows a similar, but less dramatic increase in efficiency when all 18 lift bars had water access holes and drilled to the 5/8-inch diameter (curve B 18/9 vs curve B 18/18^{+}).

Literature on industrial application of wet grinding processes indicated that reduction of the water content of a tumbling drum could increase the grinding efficiency. Considerable effort was made in testing the drums with varying reductions in water access area. No successful tests were made that sustained a higher drum output by reduction of drum water access. However, increasing the access area, as shown in Figure 14, did significantly improve performance.

It was also observed in the operation of the heavier drum (Model C), that a feed rate and operating flow that gave rpm in the range of 29 to 34, the drum would not stabilize, but would periodically surge between a high and a low rpm. It was felt that this probably was the result of changes in the water content of the drum. When the area of access holes was doubled (curve C22/22), the surging problem was minimized.

D. Occlusion of Water Access Area—After three weeks of operation of the Model C drum, with protective bars over the water access holes (Figure 15), fines were being retained by collecting under the bars, and stopping up a large portion of the water access hole area. This occlusion reduced drum grinding efficiency. The protective bars were removed and the drum operated to see if the stainless steel screening could withstand the action of the tumbling stone load. After 15 days the drum was taken back to the shop for inspection. The stainless steel screening was little affected, but 223 of the 418 holes (53%) were occluded by stones becoming stuck in them. The Model B drum was then installed and operated for 7 days without protective bars over access holes. During this operation 162 of 378 holes (43%) were blocked by stones.

Figure 15. Experimental lift bars and water access holes.

Two modifications of the lift bar design were then tested to reduce occlusion of the drum water access holes. These are shown in Figure 15. Tests are not complete, but preliminary results show that both the angled bar and the tapered hole design will probably work with the open bar and tapered holes the probable best choice. This design will probably keep the greater percentage of the hole area open. The tapered holes give the minimum contact between the stone and the metal, thus, prohibiting them from becoming stuck as in holes with vertical sides.

The reduced efficiency of the hand-loaded Otter Creek drums over extended operation (1964-1979) was probably the result of water access holes being blocked by stones. This blockage resulted in additional water containment in the drum and reduced grinding efficiency by slowing rpm and lubrication of the stone.

E. Effect of Increasing Size of Aggregate—WVU lab tests using dry grinding showed a 75 percent increase in grinding efficiency when two-inch stone was substituted for one and one-half-inch stone. In the Otter Creek wet grinding process, if the larger stone were more efficient in grinding, addition of two-inch stone at the same stabilized feed rate of the one and one-half-inch stone should cause the drum to lighten and increase its rpm. If the feed rate of the two-inch stone were then increased, the drum load would increase, slowing rpm back toward its original speed, but grinding stone at a higher use rate. Two tests were conducted on a stabilized drum by hand feeding two-inch stone in place of one and one-half-inch stone. The predicted reaction of changes in drum rpm and grinding

were observed and are shown in Figures 16 and 17. These tests indicate that using two-inch stone the wet grinding efficiency would be some 40 percent better than using one and one-half-inch stone.

Figure 16. Effect of changing stone size on drum use rate (Test No. 1, feed gate setting 4.3 cm, flow 4.9 cfs).

Figure 17. Effect of changing stone size on drum use rate (Test No. 2, feed gate setting 4.3 cm, flow 4.9 cfs).

Use of larger aggregate would require design changes in the reciprocal feeder. This may be done if the desired efficiency (120 pounds per hour at 4 cfs) cannot be achieved by the Model D drum.

Grinding Efficiency

A design goal for the self-feeding drum was a grinding efficiency that would produce 120 pounds per hour of limestone fines (90 percent 38 µm diameter or less) at an operating flow of 4 cfs. The maximum sustainable production achieved during this project segment, using the Model B drum, was 90.8 pounds per hour at an operating flow of 4.6 cfs. It is anticipated that the Model D drum will substantially improve output without the need for use of a larger size aggregate. The larger stone (2-inch) tests showed a 40 percent increase in grinding efficiency (Figures 16 and 17). Use of the larger stones, however, would require redesign of the reciprocal feeder and inverted feed cylinder and the opening of the 10-ton bin.

Samples of effluent from the drum have shown the grinding efficiency exceeding 90 percent 38 µm diameter or less. Tests during this segment used screening having 1.0 mm openings. After maximum production has been achieved with the Model D drum, screens with larger and smaller openings will be tested.

It may be beneficial in stream treatment to have neutralization from stream bottom fines. In treatment of a lake tributary stream, the smaller screen openings may be more desirable so that as much of the $CaCO_3$ as possible dissolves in the lake and little or none settles out in the lake bottom. The relationship of screen opening size, fine size production and stream bottom fines neutralization will be further studied.

Stream Chemistry

During this project segment the effect of the treatment has been studied to develop a methodology that would adequately correlate the following: (1) use rate of the drum; (2) size of fines produced; (3) ratio of dissolved, suspended and settled out $CaCO_3$; (4) changes in pH, alkalinity and acid loads of flows of sluice and stream at the treatment site and at various stations downstream; and (5) amount and effect of streambed settling out of $CaCO_3$ fines.

Optimum efficiency of the self-feeding limestone drum's grinding process has not yet been attained. The drum's present operation is sufficient to maintain pH 6.0 or above for the entire length of Otter Creek. It is felt that a two or three-drum treatment station will be adequate to treat the acid conditions of Otter Creek and maintain a native brook trout fishery. The goal of 120 pounds per hour at 4 cfs drum output should be achieved in the next project segment testing. Data gathered and analysed in Job 1 indicates the Otter Creek self-feeding drum system will effectively and economically treat the acid conditions of the Cranberry River. A more in-depth analysis will be presented in the next segment's report.

TABLE 7.1

DISSOLVED CARBONATE EQUILIBRIUM DEFINITIONS

(after Stumm and Morgan)

Species:

CO_2 (aq), $H_2CO_3^*$, HCO_3^-, CO_3^{--}, H^+, OH^-

$H_2CO_3 = H_2CO_3^* + CO_2(aq)$

H_2CO_3 = "true" H_2CO_3

Equilibrium Constants:

$k_1 = [H^+]\,[HCO_3^-] \,/\, [H_2CO_3]$ $(10^{-6.46}$ @ $10^oC)$

$k = [H^+]\,[CO_3^{--}] \,/\, [HCO_3^-]$ $(10^{-10.49}$ @ $10^oC)$

$k_w = [H^+]\,[OH^-]$ (10^{-14})

Concentration Conditions:

$C_T = [H_2CO_3] + [HCO_3^-] + [CO_3^{--}]$

Ionization Fractions:

$\alpha_0 C_T = [H_2CO_3]$

$\alpha_1 C_T = [HCO_3^-]$

$\alpha_2 C_T = [CO_3^{--}]$

$\alpha_0 = (1 + k_1/[H^+] + k_1k_2/[H^+]^2)^{-1}$

$\alpha_1 = (1 + [H^+]/k_1 + k_2/[H^+])^{-1}$

$\alpha_2 = (1 + [H^+]/k_2 + [H^+]^2/k_1/k_2)^{-1}$

Alkalimetric Titration:

$f = C_B/C_T = \alpha_1 + 2\alpha_2 + ([OH^-] - [H^+]) / C_T$

$[alk] = C_T(\alpha_1 + 2\alpha_2) + [OH^-] - [H^+]$

Buffering Intensity:

$\beta = 2.3\,([H^+] + [OH^-] + C_T\,[(\alpha_1\alpha_0 + \alpha_1\alpha_2) + 4\alpha_2\alpha_0])$

2. QUAKAKE TUNNEL WATER QUALITY

Initial Investigations - 1973/1974: Prior to the design of the prototype installations, the tunnel discharge was sampled and flows were measured twice monthly from March 10, 1973 to May 29, 1974. Six monitoring stations were established at the locations shown in Appendix "A". The monitoring station at the tunnel portal was equipped with a Leupold Stevens Type F continuous water level recorder. Flow measurements were obtained using a propeller type "Ott" current meter. Water samples were collected in plastic bottles and shipped to the commercial water quality laboratories then under contract with the Department of Environmental Resources.

Monitoring stations downstream of the Tunnel were established to provide data on the impact of the Tunnel discharge on the receiving stream. Comparison of flows and water quality, taken on the same day, allowed an evaluation of the dilution effect from the unpolluted watersheds. Water quality monitoring results, tunnel discharge hydrographs and mass curves and precipitation data are presented in Appendix "A". A summary of the tunnel flow and quality data for the 1973/1974 samplings is presented in Table 2.1. This data formed the basis for the design of the demonstration prototypes.

Prototype Operation 1979/1980: Additional samples of the Quakake AMD discharge were collected and tested during the operation of the prototype facilities between July 10, 1979 and May 21, 1980. During this period, 238 untreated water samples were analyzed. A statistical summary of the various AMD parameters for this time period is presented in Table 2.1 for comparison with the initial test data.

Figure 2.1 presents the acidity, sulfate and metals concentration, grouped according to pH range showing that higher pollutant loadings are generally associated with decreasing pH.

TABLE 2.1 - FLOW AND QUALITY DATA FOR THE QUAKAKE DISCHARGE

3. PRE-DESIGN INVESTIGATIONS

Literature Review: A survey of recent literature pertinent to the treatment of acidic waters with crushed limestone was conducted prior to the formulation of the design process.

Early significant literature was concerned with the neutralization by crushed limestone of such acidic industrial wastes as nitrocellulose manufacturing wastes (6) and steel pickling liquors (7, 8). This work led to recommendations for the design of processes to treat these particular wastes. However, the applicability of the results of these methods to the treatment of acid wastes other than those studied is uncertain. Moreover, no reported use of these processes in the neutralization of acid mine drainage was found.

It is reported (9) that there had been a number of previous attempts to use crushed limestone as static beds placed in flumes to neutralize mine drainage. However, these processes were abandoned when coating of the limestone surface by metal hydroxides severely reduced the degree of AMD neutralization obtained within a short time after starting the process.

Autogeneous mills filled with crushed limestone have been successfully used in the neturalization of acidic water in pilot installations by Mihok (10) and others. The continuous abrasion caused by the tumbling movement of the pieces of crushed limestone over each other produced very fine particles (400 mesh grain size). The surface area to particle weight ratio is larger for fine particles than for coarsely crushed stone. Consequently, as AMD flows through the drum, the presence of fine particles increases the reaction rate and accelerates the neutralization process. Also, the continuous abrasion of the crushed limestone exposes fresh surfaces over the crushed limestone and reduces the effects of stone coating phenomenon.

Lovells (21) work at the Hollywood experimental station of the Pennsylvania State University indicates that complete neutralization of AMD can be achieved by a revolving drum. In the Hollywood Plant, an autogeneous mill filled with crushed limestone and driven by a 25 horsepower motor was used to neutralize AMD flow at a rate of 0.5 cfs.

Frequently quoted is Hill and Wilmoth's (11) state of the art paper on the use of limestone to neutralize acid mine drainage, in which the observation is made that grinding of limestone to increase its reactivity, may raise its cost above that for lime.

Progress toward rationalization of the chemical and hydraulic processes occurring in the limestone neutralization processes has been made by a number of independent investigations at the Pennsylvania State University. In one such investigation (12), crushed limestone or discs cut from limestone were exposed to acidic water under a variety of conditions and the temperature coefficient and effect of flow velocity evaluated. Another investigation was conducted to evaluate the kinetics of exsolution of carbon dioxide as a function of temperature, ionic strength, and water turbulence (13). Jarret and Kountz (14) investigated the principle reaction between sulfuric acid and limestone and formulated a barrier design procedure.

Based on the results of laboratory studies, the Pennsylvania Department of Mines and Mineral Industries constructed six limestone barriers during 1970/71 in streams of the Trough Creek watershed (15). The barriers were installed to alleviate the acid-

pollution of the streams caused by coal mining in the watershed. In June 1972, high streamflows resulting from the Hurricane Agnes damaged or demolished five of the barriers. Three barriers were reconstructed and completed in November 1972. Stream water quality was monitored prior to and after construction of the barriers under a joint federal/state program. Another monitoring program was initiated by the Land and Water Research Institute of the Pennsylvania State University to evaluate the mechanisms that operate in limestone barriers and to provide for a more rational design (17).

These studies included a pilot-plant scale evaluation of the joint influence of the two rate-limiting chemical reactions on the overall performance of the process. These reactions are, first, the attack of limestone by acidic water and, second, the exsolution of carbon dioxide that is generated by the limestone dissolution.

Reaction rates are expressed per unit area of reacting surface (e.g. stone surface area) and are related to such environmental conditions as temperature, ionic strength, and flow turbulence. Differential equations expressing rates of the two limiting reactions are solved simultaneously to describe the overall neutralization process for comparison with data obtained from operation of the pilot plant (16).

The mathematical model developed for the limestone neutralization process from the pilot plant operating data was applied to predict the performance of the prototype limestone barriers operating in Trough Creek. Results showed that when the interstices within crushed limestone became clogged by silt or by iron or aluminum hydroxide, the limestone became inactivated as the acidic water had no access to the reactive surfaces. In free flowing streams, where no such clogging occurred, the reactivity of the limestone was 20 percent of the reactivity of clean stone as a result of the inhibitory effects of the coatings that formed on the stone. At lower concentrations of metallic ions no iron or aluminum hydroxide coatings accumulated, but a coating of clay-like material developed on the stone. As a result of this work, design procedures for limestone neutralization processes were developed (2).

The exsolution of carbon dioxide has an increased effect on the performance of the process as the final pH of the water rises above 5.0. Downstream of the limestone neutralization process the pH will continue to rise as carbon dioxide is lost from the water. Stumm and Morgan (18) deal with many of the chemical equilibria that pertain to the neutralization process. Their formulations provide a basis for estimating water quality after the carbon dioxide reaches equilibrium with the atmosphere.

Successful neutralization of a lightly buffered acidic stream by the use of crushed limestone filled drums was reported by Zurbuch (19, 20). The method was demonstrated at the Otter Creek installation in the Monongahela National Forest, West Virginia. The neutralization of Otter Creek raised the pH values from less than 5.1 to over 7 and sustained fish life in 12 miles of stream. This project was unique in that the power for grinding the limestone is obtained from the acid water itself. The drums were fitted with vanes and operated as overshot water wheels, utilizing the power of the stream for self-neutralization. Each drum was 44 inches wide and 50 inches in diameter. The inner drum containing the limestone was 34 inches in diameter. A minimum flow of 0.5 cfs was required to rotate a drum and agitate the crushed limestone. Flows exceeding 4 cfs were diverted to a second drum. The success of the Otter Creek installation encouraged Pearson and McDonnell to investigate the hydraulic, mechanical and chemical process design of the drums (3).

Of the literature reviewed, only Pearson and McDonnell (1, 2, 3) proposed rational and comprehensive design procedure based on both empirical and theoretical considerations. Accordingly, theoretical design of the chemical processes was determined in accordance with their proposed procedures.

Pre-design Chemical Testing: A limited number of laboratory and field tests using the Quakake AMD and limestone were conducted prior to the design. The tests were made to confirm that the behavior of the proposed prototype would be at least partially predictable by the theoretical methods used for design. The tests consisted of bench (laboratory) tests and field tests. In the bench tests, a known weight of limestone was placed in a known volume of AMD and the rate of change of pH with time was recorded. The experimental data generally confirmed the order of magnitude of the limestone loading required to produce a final pH of 6.

In order to evaluate the chemical coating which forms on the limestone particles field tests were made. These tests were made by submerging limestone chips in the tunnel discharge until the coatings developed. The limestone and coating were examined at the Pennsylvania State University by X-Ray diffraction techniques and scanning electron microscopy. These analyses indicated that the chips have three coatings:

(a) An overall coating of recrystallized calcite which is relatively porous;

(b) A brown coating rich in iron, which is not as porous and flakes off when dry;

(c) An off-white coating similar to (b), rich in aluminum and sulfur.

The exact chemical composition of the compounds in (b) and (c) could not be determined.

In general, the chemical tests indicated that the proposed design methods were reasonable and prototype design proceeded on that basis. A summary of the test methods and results is presented in Appendix "B".

4. PRINCIPLES OF AMD NEUTRALIZATION BY CRUSHED LIMESTONE

The following outlines of the chemical principles involved in the neutralization process are presented to facilitate an understanding of conventions used to evaluate the data obtained at the Quakake Tunnel.

Chemical Reactions: The neutralization of acidity by crushed limestone is controlled by the following chemical reactions:

$$CaCO_3\,(s) + H^+ = Ca^{++} + HCO_3 \qquad \text{(Limestone Dissolution)} \qquad (4.1)$$

$$HCO_3^- + H^+ = H_2CO_3 \qquad \text{(Carbonate Equilibrium)} \qquad (4.2)$$

$$H_2CO_3 = H_2O + CO_2\,(g)\uparrow \qquad \text{(Carbon Dioxide Exsolution)} \qquad (4.3)$$

Where H_2CO_3 = Dissolved Carbon Dioxide

HCO_3^- = Bicarbonate

Because the first reaction upsets the equilibrium between the bicarbonate and dissolved carbon dioxide, part of the bicarbonate formed reacts with hydrogen ions to form dissolved carbon dioxide. The formation of dissolved carbon dioxide by the second reaction in turn upsets the natural equilibrium between dissolved carbon dioxide and the level of carbon dioxide in the atmosphere. As a result, there is a chemical driving force for dissolved carbon dioxide to transfer from water to air, as represented by the third reaction.

Reaction Rates: Reactions involving only one phase (solid, liquid or gas) are usually faster than multi-phase reactions that are limited by rates of transfer of materials across the surface separating the phases. Thus, the reactions of Eq. 4.1 and Eq. 4.3 which occur across the liquid-solid limestone surface and across the liquid-gas water surface respectively, are much slower than the rate of Eq. 4.2 that occurs in the liquid phase and is instantaneous for all practical purposes.

The rates of Eqs. 4.1 and 4.3 depend on the rate constant and order of each reaction, the limestone surface area per unit flow for Eq. 4.1 and the water surface area per unit flow for Eq. 4.3. The reaction rates are influenced by temperature, ionic strength and the intensity of turbulence, but the range of their effects is minor and invariant. Consequently values for average conditions can be assumed for practical design procedures. Equations 4.1 and 4.3 have been found experimentally to be first order with respect to the concentrations of reactants (14). This means the reaction rate in Eq. 4.1 is directly proportional to the concentration of mineral acidity (hydrogen ions) in the AMD. Similarly the reaction rate in Eq. 4.3 varies directly with the concentration of dissolved carbon dioxide. Equations 4.4 and 4.5 define the change of mineral acidity and carbonic acidity with respect to the limestone surface area and the free water surface:

$$-\frac{d[H^+]}{d\alpha} = k_1[H^+] \qquad (4.4)$$

$$-\frac{d[H_2CO_3]}{d\beta} = k_3[H_2CO_3] \qquad (4.5)$$

in which:

[ ] = Concentration - moles
α = Surface area of crushed limestone per unit flow of AMD, sec-m^{-1};*
β = Free water surface area per unit flow, sec-m^{-1};
k_1 = Proton effective diffusion rate constant
k_3 = Carbon dioxide diffusion rate constant

* (area in m^2)/(Flow in m^3/sec) = sec-m^{-1}

Pilot scale investigations (16) under laboratory conditions have shown that the rates of Eqs. 4.1 and 4.3 under standardized conditions of no turbulence, 10°C temperature and an ionic strength of 0.001 kg mole-m^{-3} are:

k_1 = 0.0055 m-sec^{-1}
k_3 = 0.00058 m-sec^{-1}

Acidity and Alkalinity: The alkalinity of a water is the capacity of that water to accept protons (e.g. hydrogen ions - - [H^+]). Conversely the acidity of a water is the capacity of that water to donate protons. Alkalinity and acidity are measured by the procedures specified in "Standard Methods" (22). Acidity is measured by titrating the water to a pH of 8.3 where the concentrations of acid, base and carbonate are equal. The proton condition of a pure carbonate solution at the pH = 8.3 end point is:

$$[H_2CO_3] + [H^+] = [CO_3^{2-}] + [OH^-] \tag{4.6}$$

At low pH values the solution contains strong acids such as H_2SO_4. In this case the solution is said to contain mineral acidity or free acidity. The concentration of mineral acidity is commonly measured by titrating the solution to the methyl orange acidity end point of pH = 4.5. The proton condition of a pure solution at this end point is:

$$[H^+] = [HCO_3^-] + 2[CO_3^{2-}] + [OH^-] \tag{4.7}$$

When the initial pH of a solution is greater than 4.5 the solution is titrated with a strong acid to the methyl orange end point. The concentration of acid required to accomplish the titration is termed alkalinity.

Alkalinity and acidity are formulated as follows:

$$[Alk] = [HCO_3^-] + 2[CO_3^{2-}] + [OH^-] - [H^+] \tag{4.8}$$

$$[Acy] = [H_2CO_3] - [CO_3^{2-}] - [OH] + [H^+]$$

in which:

[Alk] = alkalinity in kg mole-m^{-3}

[Acy] = acidity in kg mole-m^{-3}

[H^+] = is interpreted to include protons released by hydrolysis of metals and by dissociation of non-carbonic weak acids, as well as from mineral acidity

Alkalinity Change as a Measure of Neutralization: The change in alkalinity is a measure of proton consumption as the reaction proceeds. The value of alkalinity as described by eq. 4.8 can be computed for the controlling chemical reactions; Eq. 4.1, 4.2 and 4.3.

The first reaction removes one proton from solution thereby increasing the alkalinity by one unit. It also adds a bi-carbonate ion resulting in a net alkalinity increase of 2 units. The remaining two reactions do not affect the alkalinity concentration as shown below:

$$CaCO_3\,(0) + H^+\,(-1) = Ca^{++}(0) + HCO_3^-\,(+1) \qquad Alk = +2 \qquad (4.1)$$

$$HCO_3^-\,(+1) + H^+\,(-1) = H_2CO_{3(0)} \qquad Alk = 0 \qquad (4.2)$$

$$H_2CO_3\,(0) = H_2O\,(0) + CO_2\,(0) \qquad Alk = 0 \qquad (4.3)$$

($\pm$) = Positive or negative alkalinity unit

Equating the incremental decrease in proton concentration by Eq. 4.1 to the incremental increase in alkalinity:

$$d[H^+] = 0.5\ d[Alk] \qquad (4.10)$$

Eq. 4.4 can then be transformed to reflect the alkalinity change throughout the neutralization process:

$$0.5\ \frac{d[Alk]}{d\alpha} = k_1[H^+] \qquad (4.11)$$

The value of [Alk] is dependent on the concentration of carbonate and protons in the solution as described by Eq. 4.8. The total concentration of carbonate in solution is described by:

$$C_t = H_2CO_3 + HCO_3^- + CO_3^{--} \qquad (4.12)$$

and if Eqs. 4.8 and 4.9 are combined, we find:

$$C_t = [Alk] + [Acy]$$

Where C_t = the total concentration of carbonate, kg-mole-m^{-3}

Alkalinity can be formulated in terms of C_T and H^+ as follows:

$$[Alk] = \frac{C_t}{1 + [H^+]/K_1} - [H^+] \qquad (4.13)$$

Where K_1 is the first dissociation constant for carbonic acid.

Eq. 4.13 disregards the $[OH^-]$ and $[CO_3^{--}]$ concentrations as they are very small in the pH range of interest. Table 7.1 presents a complete description of the carbonate equilibrium system.

A numerically soluble expression describing the neutralization process can be obtained by calculating the derivative of Eq. 4.13 with respect to $[H^+]$;

$$\frac{d[H^+]}{d\alpha} = \frac{2k_1[H^+]}{(1 + K_1C_t/(K_1 + [H^+])^2)} \qquad (4.14)$$

Roughly translated, Eq. 4.14 states that the change in protron concentration with respect to the neutralization opportunity (i.e., stone surface area, AMD volume, contact time) is a function of the concentrations of protolized ions (e.g. H^+, Al^{++}, Fe^{+++}) and the inorganic carbon (i.e., Acidity + Alkalinity).

Inorganic Carbon Balance: The solution of Eq. 4.14 is complicated by changes in concentration of inorganic carbon concentration during the neutralization process. During neutralization, the carbonate concentration is increased in the AMD at a rate equal to the rate of dissolution of limestone, according to Eq. 4.1. This increase in inorganic carbon concentration is offset by a decrease due to the expulsion of carbon dioxide from solution. The rate of carbon dioxide exsolution is proportional to the concentration of carbon dioxide present in solution, as Eq. 4.5 shows. The total incremental change in concentration of inorganic carbon is expressed by the differential:

$$dC_t = K_1 [H^+] d\alpha - k_3 \frac{C_t}{1+K_1/[H^+]} d\beta \qquad (4.15)$$

which may be written:

$$\frac{dC_t}{d\alpha} = k_1[H^+] - k_3 \frac{C_t}{1+K_1/[H^+]} \frac{d\beta}{d\alpha} \qquad (4.16)$$

The linked differential Equations 4.13 and 4.16 can be solved by numerical methods. The solution mathematically models the neutralization process for given initial concentrations of protons and C_T and for given treatment conditions. The treatment conditions being the limestone and free water surfaces provided per unit flow.

Limestone Characteristics: The neutralization characteristics of crushed limestone depend on both the physical and chemical properties of the stone. Particle size and shape control both the hydraulics of flow through the crushed stone and the surface area of $CaCO_3$ available for reaction with the acid water. Hardness of the stone determines the rate of abrasion and chemical dissolution of the stone, which is related to the Magnesium Carbonate ($MgCO_3$) content of the stone.

The hardness of the limestone was measured by the Los Angeles Abrasion Test (ASTM C-131) which consists of rotating an aggregate sample in a 28-inch diameter drum at a speed of 30 to 33 RPM for 500 revolutions. The fine material ground from the original sample is discarded and the difference between the original weight and the final weight, expressed as a percentage, is reported as the percent L.A. Abrasion wear. Zurbuch (20) found that this abrasion test method correlated well with observed limestone use rates in revolving drums.

The rate of dissolution of limestone is dependent on its magnesium carbonate content. It appears that the rate of dissolution of a limestone is inversely proportional to its $MgCO_3$ percentage. Pearson (16) derived this relationship from data presented by Hoak, Lewis and Hodge (8).

Shape Factor: The shape factor of the crushed limestone particles is required to determine for the the surface area per volume of stone and computations of flow through the beds of crushed limestone. The shape factor is defined as:

$$\frac{V}{A} = \frac{SD}{6} \qquad (4.17)$$

where:

S = Shape factor
D = Nominal particle diameter, equal to the diameter of a sphere of the same volume
V = Volume of the particle
A = Surface area of the particle

This equation defines the shape factor as the ratio of the surface area of a sphere with the same volume as the particle, to the surface area of the particle. Previous investigators (23) estimated the shape factor-surface area relationship by individual measurements on more than one ton of crushed limestone. For 1,218 stones, the mean shape factor was 0.76 with a standard deviation of 0.04 and a range of 0.59 to 0.89. Accordingly, a shape factor of 0.76 was used for design of the prototypes and evaluation of the operating data.

Reactivity Coefficient: The rate constant for the dissolution of limestone by AMD was determined experimentally for clean limestone in the laboratory. But, it has been observed that limestone placed in natural streams carrying AMD develops a surface coating of sediment, aquatic organisms and/or heavy metal oxyhydrates, depending on the chemical make up of the AMD. Comparisons between observed and predicted performances of four limestone barriers in the Trough Creek Watershed, Pennsylvania (17), indicate that both sediment/biological coatings, and the heavy metal oxyhydrate coatings reduced the reactivity of the limestone. At Trough Creek, the reactivity of the limestone was found to be 20 percent of the reactivity obtained for clean limestone under laboratory conditions. This factor of 20 percent has been termed the reactivity coefficient, and describes the effect of the thin film that forms on the stone surface which inhibits the neutralization process. It does not account for those surfaces of the limestone which are unsubmerged in AMD or blanketed by sediment, nor does the factor account for the deposit of metal oxyhydrates in the pores between the stones.

Load Factor: For design purposes, it is convenient to express the ratio of reactive limestone surfaces to AMD volume (α in Eq. 4.4) in terms of commonly used stone and flow measurements. Therefore α (in $sec\text{-}m^{-1}$) is converted to Load Factor (LF) in terms of tons of limestone per cfs of AMD per inch of stone size.

$$LF = \frac{Wr\ (TONS)}{pSQD(in)(cfs)} \qquad (4.18)$$

in which:

W = mass of crushed limestone, tons;
D = diameter of crushed limestone, inches;
Q = AMD flow, $ft^3\ sec^{-1}$;
S = stone shape factor
r = limestone reactivity coefficient; and
p = percentage magnesium carbonate in limestone (1.0 for limestone containing 1% $MgCO_3$, or less)

5. PROTOTYPE DESIGN AND CONSTRUCTION

The Quakake Tunnel prototype installations were designed and constructed during 1978 and 1979. A total of 30 individual process units representing variations of 4 basic design processes were installed. All the units employed crushed limestone for neutralization of AMD. The installed processes included both static and abrasive processes and are characterized in Table 5.1. The combined treatment capacity of the prototypes was 3 cfs. Flow was delivered to the units by a turbine pump capable of delivering 1800 GPM at a 50 foot head. A schematic layout of the project is presented in Figure 5.1 and aerial views are shown in the frontispiece.

Pumping of a portion of the AMD to the treatment units was employed for the prototype demonstration rather than gravity flow which is envisaged for a permanent project. Pumping was used to minimize site work and disturbance of adjacent woodlands as the use of the land for the project was obtained through gratis easements. It is intended that a permanent treatment facility would not require outside power sources to operate the treatment units.

Figure 5.1 Prototype Project Layout

Limestone: Crushed limestone for the demonstration project was obtained from two sources. A high calcium limestone from the Bethlehem Mines Millard Quarry in Annville, PA, was selected for use in all the prototypes. In addition, a high magnesium limestone was obtained from local sources for comparative use in the tumbling drums. Three sizes of the high calcium stone were used. The chemical and physical properties for both limestones are as shown below.

TABLE 5.2 - CHEMICAL AND PHYSICAL CHARACTERISTICS OF PROCESS LIMESTONES

Characteristic	High Calcium Limestone			High Magnesium Limestone		
	Mean	Min.	Max.	Mean	Min.	Max.

Figure 5.3 Limestone Static Barrier Construction

Static Barriers: Ideally, the problem of neutralizing an acid stream might be solved by the simple method of placing a sufficient amount of limestone as a bed or barrier, directly in the stream. However, during previous attempts to implement this method, the limestone became coated with metal complexes and the stone became clogged by stream sediments. These problems could have been partially the result of design deficiencies since both laboratory studies and evaluation of the Trough Creek Limestone Barrier Project (14, 15, 17) indicated that the use of instream barriers was feasible under certain conditions. The conditions which favor the use of limestone beds are low stream discharge variations, low sediment load and low iron content. These criteria were used in the selection of the Quakake Tunnel Project site. Also, the diversion of a constant amount of flow to the prototypes in the demonstration project eliminated flow variations. Standard sanitary septic tanks were used as combination diversion/sedimentation tanks. They were designed to remove sediment sizes greater than the sizes which would theoretically be carried through the stone voids by the flowing water.

Previous research identified the parameters considered to govern the neutralization process. They include the following:

Stone and AMD composition,
Available Limestone Surface (stone size and shape),
Contact time, Streamflow and Temperature,
Water Turbulence - Hydraulic Shear Forces, and
CO_2 Exsolution Subsequent to Neutralization.

The prototype limestone barriers were designed to explore the response of the process to variations in stone size and hydraulic characteristics. Prior studies indicated that under barrier conditions of near constant flow and low iron and sediment loads, the reduction in reactivity due to fouling of the limestone surfaces did not fall below 20% of that for fresh clean stone. Accordingly, all the barriers were sized to provide 5 times the limestone surface area per unit flow of AMD (Load Factor) above that required by theory to achieve the desired degree of neutralization using clean crushed stone.

Each barrier was subdivided into individual units, (bins) within which limestone was placed. This provided convenient sampling points along the treatment path and allowed adjustment of hydraulic gradient through the barrier. The use of adjustable weir plates between the bins provided control of stone submergence and hydraulic gradient through the stone. The limestone barriers were constructed in plywood channels lined with 20 mil. PVC. Divisions were created within the barriers by using wooden frames covered with heavy diamond wire mesh and 1/4 inch hardware cloth. Figure 5.3 shows construction details of the six barriers. The flow to the inlet of each barrier was measured using a 90° v-notch with a plywood stilling box. The dissipation of flow energy into the stilling boxes was accomplished by using slotted PVC pipes fitted with end caps.

Filter-Type Units: The filter-type processes consisted of the installation of three parallel sets of six filter units. The units were designed to operate in three modes; downflow, upflow and alternating downflow-upflow. Construction details are illustrated in Figure 5.4.

An upflow method of operating was reported to have been successful in the treatment of steel pickling liquors (7,8). In upflow process, abrasion of the limestone particles is created by maintaining the bed in a constant fluidized condition. In the downflow design, the beds act as a static barrier but they have the capability of being backwashed to remove the buildup of sediments and coatings. Backwashing is initiated by closing the bottom gate valves and operating the units in the fluidized upflow mode. The alternating flow units were designed as downflow units with automatic backwashing capabilities.

Downflow operation was achieved by opening the bottom gate valve allowing AMD to percolate downward through the stone and through the gate valve to the next unit. By closing the bottom gate valve, the operation converted to the upflow mode, wherein AMD entered the bottom chamber, flowed upward to fluidize the stone, and then passed through the slotted control valve to the base of the next unit downstream. For operation in the alternating flow mode the slotted control valve was replaced by a siphon. The bottom gate valves were partially operated and the unit operated in a down flow mode. The siphon discharged to the base of the next downstream unit causing an upflow flushing of the downstream unit.

Figure 6.4 Construction Details of Filter-Type Units

Tumbling Drums: Rotating drums containing crushed limestone act as grinding mills to produce fine limestone particles which are highly reactive with AMD. Motor powered tube mills and limestone filled water wheels for neutralization of AMD and slightly acid streams have been successfully demonstrated (10, 19, 20, 21). The success of the unique drums demonstrated by Zurbuch, coupled with the subsequent analysis of the chemical and hydraulic/mechanical processes of the drums by Pearson and McDonnell led to the design and installation of similar units at the Quakake Tunnel site.

Of the five drums installed at Quakake, three drums (Drums 2, 3 and 4) were installed in series as an integrated treatment unit. One drum (No. 5) placed separately to treat the effluent from the static barriers provided data on combining the two methods. The remaining drum (No. 1) located in the stream channel, below the diversion dam, provided information on flows exceeding the capacity that could be delivered through the pumped distribution system (1± cfs). A typical drum installation is illustrated in Figure 5.5.

The five drum installations were constructed identically. Drum bays were constructed of 6 inch cinder block walls placed on 6 feet, 8 inch square by 8 inch thick concrete pads. The front bay walls were erected 4 feet high for splash containment. The bay side walls were 2 feet high in order to facilitate loading and unloading and periodic checks of the drum contents.

The drum shell was constructed from 3/8 inch thick steel pipe with an inside diameter of 3 feet and a length of 18 inches. Welded to both ends were 3/8 inch thick, 4 feet 8 inch diameter end plates. Welded between each end plate were sixteen curved water wheel vanes, having a 10 inch radius, which functioned as water containing buckets. The curved metal vanes were cut from standard steel pipe. Half-inch diameter holes were drilled through the inner drum at the base of each bucket to allow water to enter the drum and wash out the limestone fines generated by the tumbling stone in the drums. Baffles of 1/4 inch thick by 2 inch angle iron were bolted to the inside of the drum surface at the base of each vane to prevent slippage of the stone mass. A hinged door, bolted shut during operation, allowed loading of limestone into the drum. The drums were supported by 2 inch steel axles seated in pillow blocks with sealed ball bearings which rested on structural steel angle tripods.

Lovell (21) noted that noise is a drawback associated with operation of the drums. Zurbuch (19) significantly reduced this problem by lining his drums with a steel reinforced rubber mat. The Quakake drums were provided with a similar liner. Consequently noise levels created by the drums were not objectionable.

Autogenous Mill: The method of passing AMD through motorized rotating tubes partly filled with crushed limestone has been used to neutralize AMD. One such installation was transferred from its original Hollywood, Pennsylvania location to the Quakake Tunnel site prior to the third sampling period. The mill, shown in Figure 5.6, is a steel drum 5 feet in diameter and 20 feet long. The drum which rests on idlers is rotated by a 25 HP electric motor. The operation of this unit as an autogenous mill has been previously reported (21).

The mill was used at Quakake to investigate the concept of mechanically cleaning a static bed. The drum was used as a stationary limestone bed with periodic revolutions to achieve stone cleaning, rather than the production of fines. The bed was turned through two revolutions every four or eight hours. The drum was filled approximately one-half of its capacity with 5mm (1/4 inch) limestone.

6. PROTOTYPE OPERATION

The Quakake Tunnel prototypes were operated periodically over a 2-year period. The facility was operated for four separate sampling periods (runs) as follows:

Run No.	Sampling No.	Begin-End Dates
1	1 thru 12	7/10 - 10/4/79
2	13 thru 39	11/12 - 11/21/79
3	40 thru 65	5/19 - 5/21/80
4	66 thru 83	7/20 - 7/25/81

The non-operating periods were used for the chemical analysis of samples, evaluations of results, planning subsequent runs, and modification or repair of the plant.

Monitoring and Analytical Procedures: For samplings 1 thru 65, a 500 mL sample and a 125 mL acidified sample were taken at each sampling point. Bottles were rinsed before filling, capped underwater and stored at 9°C until shipping to the laboratory in ice-packed containers. Chemical analyses were performed at the Harrisburg Laboratory of the Pennsylvania Department of Environmental Resources. All samples were tested for the following parameters:

pH;
free acidity
total acidity;
alkalinity;
iron (total and ferrous);
sulfate;
aluminum;
calcium.

Occasional determinations were also made of:

manganese;
magnesium;
sodium;
potassium;
silica;
chloride;
solids (total and suspended).

The following field measurements were also made at each sampling:

pH;
temperature (water and air);
flow rate (by weirs);
hydraulic head; and
stone load and RPM for tumbling drums

During Run No. 4, the pH, alkalinity and acidity were determined on site.

Results of the monitoring program are presented in Appendix "C".

Run No. 1: Initially, the plan of operation for the demonstration project anticipated a 6-month operating period with twice-weekly samplings. This procedure was followed for samplings 2 through 12. Sampling No. 1 was a false start as the project operation was halted by a malfunction of the generator which supplied power to the pump. Figure 6.1 shows the operation schedule for Run No. 1.

Figure 6.1 Operation Schedule - Run No. 1

During Run No. 1, several problems developed which required correction. The siphon units in the alternating filter units did not function because they were unable to develop sufficient head to purge the air in the pipes between the units. To correct the situation, the siphon in the upper unit was replaced with a mechanical flusher, while the siphon in the third unit was replaced by a commercial sanitary siphon with non-pressure discharge. Both modifications worked satisfactorily, although the modification of the backwashing equipment required the removal of some of the stone, thereby reducing neutralization capability. Having demonstrated the feasibility of automatic backwashing on some of the units, the remaining filter-type units were backwashed manually.

Major problems were encountered in the units containing the 5mm (1/4") stone. The rate at which the limestone fouled was much greater than had been originally anticipated. The front face of the stone beds of barriers 2, 4a and 6 became clogged which reduced the permeability of the stone bed to the point that the AMD ran over the tops of the beds rather than through them. This was particularly problematic in barrier No. 6 which was on a 30% slope.

The permeability of the filter units was also seriously reduced by clogging. The original design of these units used an 1/8-inch screen to retain the stone at the base of each bin. These screens became almost totally clogged after 3 weeks of operation. In several instances, the upper one foot of the downflow units was actually "cemented" by the fouling coat and could not be backwashed. Mechanical prodding was necessary to break the "cemented" layer so that the stone could be cleaned. After sampling No. 8, the stone and screens were removed from the upflow and downflow units and a graded filter was placed in lieu of the screening. Also the monitoring of barrier No. 6 was halted at this time.

Evaluation of the results from the first sampling run indicated that the monitoring procedures would have to be revised in order to adequately investigate the rate of limestone consumption and fouling. It was clear that an increased sampling rate would be required because the rate at which the stone reactivity decreased necessitated hourly rather than daily measurements as had been originally anticipated. Similarly, the filter units required more frequent backwashing to maintain reactive limestone surfaces. In addition, the three to four day sampling intervals did not allow gathering

of sufficient data to describe the short term oeprations of the tumbling drums. The refilling cycle for the drums coincided with the sampling frequency approximately 3 to 4 days. As a result, the data gathered was primarily for freshly filled or nearly empty drums. Another problem associated with the drum operations noted during this run was that the detention time provided by the units was insufficient. It was observed that the AMD leaving the process units was milky colored, indicating that the reaction of the limestone fines with the AMD was not complete.

Run No. 2: The operation of the units during Run No. 2 was planned in a manner which would supplement the data gathered during Run No. 1 by utilizing shorter sampling intervals. The monitoring frequency was increased to 3 samplings per day with continuous 24-hour operation of the units.

Run No. 2, consisting of samplings 13 through 39, started on November 12, 1979. Figure 6.2 shows the operation schedule for Run No. 2.

IN OPERATION BUT NOT SAMPLED.
DRUM STONE LEVELS CHECKED.

Figure 6.2 Operation Schedule - Run No. 2

On completion of the laboratory testing of samples for Run No. 2, the monitoring results were evaluated with respect to the design theories. At this point, more than 2000 samples and measurements had been collected. Analysis of the data indicated that although design processes could be described emperically, the results did not correlate with the initial theoretical derivations. Part of this problem is related to the random nature of the data itself which is illustrated in Table 2.1 by the wide chemical variations of the AMD influent itself. The lack of agreement between the theoretical and experimental results was related to buffering effects observed in the pH 4.5 to 6.0 range. Additional correlation problems were encountered while trying to relate the measured drum operation parameters - RPM, flow and stone load, to the observed neutralization process.

As a result of the evaluations of Runs 1 and 2, the following measures were taken in preparation for Run 3:

Fresh 5 mm (1/4") limestone was placed in the filter type units after removal of the used stone.

The 5 mm (1/4") limestone in barriers 5 and 6 was replaced with 13 mm (1/2") limestone.

Facilities were added to provide detention of a portion of the effluent from the drum series 2, 3, and 4. This was achieved by diversion of 1 to 3 gallons per minute into two 55 gallon drums, providing up to 1 hour detention time for the process to continue.

Run No. 3: The third sampling run concentrated on the operation of the downflow units and revolving drums. The operation schedule is shown in Figure 6.3. The evaluation of the data from Runs 1 and 2 indicated that these processes were the most promising treatment methods. As it was felt at this time that the likely cause of the buffering problem was the carbon dioxide being generated by the neutralization process, aeration equipment was provided for the drum detention units. The autogenous mill from the Hollywood Plant was also installed at this time.

Figure 6.3 Operation Schedule - Run No. 3

Following the evaluation of Run No. 3, a draft report was prepared and tentative design procedures were proposed. The design procedures were based almost entirely on empirical data as the relationships between the observed neutralization processes and theory were not established. A fourth run was proposed in an attempt to establish this link. Marked differences between laboratory pHs and field pHs were noted in all the samplings as illustrated in Figure 6.4. The pH, acidity and alkalinity relationships are fundamental descriptors of the chemical processes in the reactions. It was questionable if the values obtained in the laboratory adequately describing the chemical process at the site. For example, the carbon dioxide content of the process effluent could not be determined in the laboratory. It was decided to attempt to solve these problems by testing the acidity and alkalinity on fresh samples in the field during a fourth run.

Figure 6.4 Field pH Determinations Compared with Lab pH The differences between lab and field values are consistant with pH levels. This suggests the chemistry of the sample has been altered between testing periods. Loss of CO_2 and continued $CaCO_3$ dissolution could contribute to these changes.

Figure 6.5 Operation Schedule - Run No. 4

Run No. 4: Run No. 4 consisted of intense sampling of the drums and upflow units for one week as shown on Figure 6.5. A laboratory trailer was provided by the Department and the chemical tests for pH, acidity and alkalinity were performed onsite on fresh samples. In addition to the standard test for hot acidity, titrations on cold unoxidized samples were made. Comparison of the oxidized titrations with the unoxidized titrations allowed a rough estimate of the carbon dioxide to be made. Intermediate readings were taken during the tests to allow comparison of the entire titration curves.

Additional objectives of Run No. 4 were the gathering of additional data on carbon dioxide stripping by aeration, sludge production in the downflow units, and the effects of increased detention time on drum process series.

Two 500 gallon tanks with aeration equipment were installed for carbon dioxide stripping tests on the tumbling drum effluent. Both flow through and batch stripping tests were made.

An additional 200 gallon tank was used to settle sludge from the downflow backwash water. Dewatering tests were performed on the settled sludge. The tests were for the rapid sludge dewatering system of U.S. Environmental Products Inc. and the results are presented in Appendix "E."

A 2,500 gallon shallow detention pond was constructed between Drum No. 3 and Drum No. 4 in order to evaluate the effect of maintaining the ground limestone fines within the process. Partial aeration was provided by a seven feet high drop into the pond with a steel edged 8 feet long weir maintaining sheet flow.

DETENTION POND BETWEEN DRUMS 3 AND 4

7. NEUTRALIZATION PERFORMANCE EVALUATION

The performance of the limestone neutralization process is evaluated in terms of the degree of decreased acidity and corresponding increased alkalinity and pH which are inter-related by chemical equilibria conditions. The original design procedures were based on neutralization kinetics observed in the laboratory and the assumption that equilibrium conditions for a pure carbonate solution would control the process. pH was assumed as the master variable.

The original design assumptions appear to be substantially correct. In Figure 7.1, observed pH values obtained in the initial run of Barrier 5 are plotted against their appropriate load factors. Theoretical curves derived by the initial design procedures are also superimposed on this figure. The two theoretical curves represent the two extreme cases of carbon dioxide exsolution (i.e., all CO_2 is retained in solution or is completely exsolved). In practice, neither of these states will be achieved and the actual results will plot between the theoretical derivations. As seen on Figure 7.1, the field results do plot within the theoretical limits. These results suggest that if suitable values for CO_2 exsolution and for the reactivity coefficient can be obtained, the design process is valid. However, when the observed alkalinity and acidity values were examined along with the pH values in terms of chemical equilibria, there appeared to be some major inconsistencies. The observed pH values are lower than the values computed by carbonate equilibria criteria computed for the alkalinity and acidity test values. Average observed pH values and pH values computed from the acidity-alkalinity test values are plotted against alkalinity in Figure 7.2. Some variations between field results and laboratory values can be expected as there is an opportunity for continued reaction within the sample bottles. However, if the basic equilibria assumptions are correct, there should not be any discrepancies between the laboratory pH, acidity and alkalinity values. The computed pH values, field pH values and the average alkalinity and acidity values used for this comparison are plotted against laboratory pH in Figure 7.3. These values are mean values for all tests taken prior to Run No. 4.

Figure 7.1 Observed pH - Load Factor Relationships. The upper and lower curves are computed values for the limiting CO_2 cases is

1. All the CO_2 generated is driven off.

2. None of the CO_2 generated by the dissolution of limestone is lost. The observed values fall between these two extreme cases.

Figure 7.2 pH Variations Compared with Alkalinity

Figure 7.3 *pH and Carbonate Parameters Compared with Lab pH These values are mean values for all tests taken prior to Run No. 4. Figures 7.2 and 7.3 were prepared to illustrate the marked differences between the pH values measured in the field and in the lab and theoretical pH values computed from the results of the Acidity and Alkalinity tests. Resolution of the cause of these differences is necessary so that the test data can be evaluated in terms of chemical equilibrium.*

Carbonate System Equilibria: The relationships between pH, acidity and alkalinity are described by carbonate systems equilibria. Table 7.1 and Figure 7.4 identify the governing species and their relationship to one another in the carbonate equilibrium system. The alkalinity and acidity in the reactions are measured by titrating the water samples with an acid or base to the appropriate end point. The titration end points correspond to the equivalence points, x, y and z in Figure 7.4 The equivalence points define the Acid or Base Neutralization Capacity (ANC or BNC).

The equations in Table 7.1 define the theoretical acid-base neutralization capacities of the carbonate systems. Alkalinity and acidity are measures of the proton excess or deficiency of a solution with respect to a reference proton level (C_t). Titrations taken to the equivalence points f = 0 and f = 1 give the alkalinity and acidity values of a sample from which C_t is obtained as the difference in the titration values between the two equivalence points.

Point y on Figure 7.4 is the phenolphthalein end point. It represents the point at which the solution's ANC is capable of neutralizing an acid concentration equal to the C_t of the solution. Point x represents the end point of the alkalinity determination by "Standard Methods" (22). At this point the solution has no acid neutralization capacity. A negative ANC is common for AMD. The amount of base required to bring the solution to f = 0 (End Point x) is termed the mineral acidity, or, equivalently, free acidity or negative alkalinity. In this range, the solution is highly ionized and H^+ added will remain disassociated; a characteristic of a "Strong Acid". In contrast, a "weak" acid is only partially ionized. Aqueous CO_2 (H_2CO_3) acts like a weak acid and the resulting acid concentration is governed by the equilibrium constants given in Table 7.1.

The relationship of concentrations of alkalinity, acidity and total carbonate species (C_t) are independent of temperature, pressure and some selected changes in the solutions chemical composition. Graphs of pH contours can be constructed using these concentrations (C_t, Alk, Acy) which can be used to investigate equilibrium conditions. On Figure 7.5 Alkalinity is plotted as a function of C_t as derived from the equations in Table 7.1. Similarly, Figure 7.6 is a plot of C_t versus Acidity. On these graphs, the addition or removal of base, acid, CO_2, $CaCO_3$ or dilutions of the solution is a vector quantity.

The problems of reconciling the test data with equilibrium theory can be illustrated by plotting a typical neutralization result on Figures 7.5 and 7.6. For example, for a lab pH of 6.0 on Figure 7.3, we obtain the following average test results:

Alkalinity	=	20 mgl
Acidity	=	2 mgl
C_T	=	22 mgl

However, when alkalinity is plotted against C_t on Figure 7.5 (point A) and acidity against C_t on Figure 7.6, a pH value of 7.5 is obtained rather than the actual test value of 6.0. In order to move the plotted Point A from the 7.5 contour to the test 6.0 contour, the addition of an acid or CO_2 concentration is required in accordance with the vector diagrams on the graphs. In the case of our example a vertical translation of the axis by 15 mgl is necessary to reconcile the test values. This indicates that the solution contains an acid other than that derived from the H^+ ion and its presence is not being detected by the acid and alkalinity test values when they are related to the pH test value.

The discrepancy between the lab test values themselves and with neutralization theory created difficulty in analyzing the results of the first 3 runs. In order to resolve this problem, an expanded testing program was proposed, which included field testing for alkalinity and acidity.

Figure 7.4 Carbonate Equilibrium Relationships
The equivalance points x,y,z correspond to pure solutions (C_TMolar) of H_2CO_3, $NaHCO_3$ and Na_2CO_3. pk is the negative logarithim of the first dissassociation constant. At this point H_2CO_3=HCO_3^-.

Figure 7.5 Theoretical Total Carbonate, pH and Alkalinity Relationship The usefullness of these graphs is based on the fact that changes in the carbonate solution can be represented as a vector. Adding a strong acid or base moves the point representing the initial solution composition vertically. Vertical lines would therefore represent titration curves. Note that changes in C_T do not affect alkalinity values In solutions that contain bases and acids other than H^+, OH^- and carbonate species, the contours in the diagrams will be displaced vertically. Therefore, if the solution represented by point A contained 15 mgl of acid caused by iron or aluminum, it would plot at point B on the 6.0 pH contour line.

Figure 7.6 Theoretical Total Carbonate, pH and Acidity Relationship Note that the addition of $CaCO_3$ to the solution does not decrease the amount of acid in solution, but adds a base.

Figure 7.7 Alkalinity Endpoint Compared to Carbonate Concentration The Alkalinity endpoint is dependant on the total carbonate content.

Field Titration Results: All the field titration tests were performed immediately after the samples were obtained. Care was taken to minimize CO_2 losses caused by over-handling and mixing. Two types of titration were performed. First, a sample was titrated before the AMD could change temperature ("Cold" titration). A second sample was boiled ("Hot" titration) in accordance with Standard Methods (phenolphthalein acidity at boiling temperature). The boiling drives off all the free carbon dioxide and promotes the hydrolysis of iron and aluminum compounds. A relative measure of the carbon dioxide content is obtained from the difference between the hot and cold acidity titrations (amounts).

Plots of the "Hot" and "Cold" titration results are presented in Figure 7.8. As expected, the "Cold" acidity values were much higher than the "Hot" values due to the aqueous carbon dioxide. However, the alkalinity titrations were not expected to show a large increase in mineral acidity. The high "Hot" acidity levels at pH's greater than 5.0 were unexpected as well.

A typical set of titration curves, presented in Figure 7.9, illustrates the effects of the carbon dioxide content and mineral acidity. The increase in mineral acidity is attributed to aluminum hydrolysis since iron levels, generally 1.0± mg/l, could not have caused the increased mineral acidity through ferrous-ferric oxidation. The "Hot" acidity values for Run No. 4 are compared with the acidity curve computed for 13 mgl of aluminum in Figure 7.10. As can be seen from this, the acidity beyond the strong (mineral) acid range is caused primarily by partially disassociated aluminum species acting as a weak acid.

Figure 7.11 suggests why the acidity caused by the aluminum species was not identified prior to Run No. 4. The low laboratory acidity values, beyond pH = 5, led to the assumption that, once the mineral acidity was neutralized, the remaining acidity would be predominately CO_2 acidity. It was also assumed that the iron and aluminum contributed primarily mineral acidity which was largely converted to a precipitate beyond pH = 5.5. The results of the field titrations in Run No. 4 show these assumptions to be incorrect, indicating that the chemical evaluation of the neutralization process is more complex than previously assumed.

Figure 7.8 Comparison of Hot & Cold Acidity - Alkalinity Tests

Figure 7.9 Typical Field Titration Test Results
The differences causing Zone A are attributed to mineral acid formation by oxidation while Zone B represents the differences in CO_2 concentrations.

Neutralization Computations: The numerical model of the neutralization process was modified since the previous model considered only carbonate alkalinity and buffering. As previously shown, the addition of terms for the aluminum species would have been sufficient to adequately model the Quakake AMD, but in order for the procedure to have a more general application, the acidity due to ferric and ferrous iron species was included. Consequently, the alkalinity term was redefined as:

$$
\begin{aligned}
[Alk] = \; & [HCO_3^-] - [H^+] - [HSO_4^-] \\
-3 \; & [Al^{+3}] - 2[Al(OH)^{+2}] - [Al(OH)_2^+] \\
-3 \; & [Fe^{+3}] - 2[Fe(OH)^{+2}] - [Fe(OH)_2^+] \\
-2 \; & [Fe^{+2}] - [Fe(OH^+)]
\end{aligned}
$$

The strength of the acidity contributed to the solution is computed in terms of ionization fractions by procedures similar to those used for the carbonic system. The expressions representing all species become extremely cumbersome as the Iron and Aluminum ions are polyprotic (i.e. able to donate more than one proton). Therefore, the species included were limited to those species having the greatest effect on the system (i.e. those with an equilibrium constant within or close to the (H^+) concentrations representing the range of pH under consideration; A pH = 3.0 to 8.3). Even with these limitations, the governing equations are lengthy. A detailed description and derivation of the computation procedures are presented in Appendix "D." The relative importance of the various acid forming elements are shown in terms of acidity (Figure 7.12) and buffering intensity (Figure 7.13). Buffering intensity represents the resistance to pH change provided by a particular element of the AMD system.

LIMESTONE COLUMN TEST

A limestone AMD neutralization column was tested at a Canadian mine-mill complex. An excerpt from the report on these tests provides some insight into some further aspects of limestone use for this purpose. Further details on the use of a limestone column might be available from one of the NORANDA employees involved who is now a consultant, or from Noranda Research.

FURTHER LABORATORY STUDIES

Introduction

Although the pilot plant studies had indicated no positive advantage of limestone neutralization for the strong [redacted] drainage, it was felt that the process might be successful with weaker minewaters. It was hoped to include a period of limestone neutralization in the final demonstration run with the weaker [redacted] drainage. It was recognized, however, that a comprehensive laboratory evaluation was required to define as closely as possible the performance to be expected from the pilot column. In the light of previous experience, long laboratory runs were planned and in the first phase a synthetic minewater was used which corresponded closely to the actual Heath Steele drainage. In the second phase, conducted at the pilot plant, actual minewater and local limestone were used. Thus any difference between the pilot and laboratory results could be attributed to scale-up effects.

Operations

The column used in these laboratory studies was 2.44 m (8 ft.) high, 3.81 cm (1.5 in.) in inside diameter and was constructed of transparent acrylic material. All column joints were sealed with rubber gaskets. The minewater was pumped upwards through the column and the effluent was carried from the top of the column through a length of Tygon tubing. A 1.22 m (4 ft.) bed of crushed limestone was supported by a distribution plate with 2.4 mm (0.094 in.) diameter holes on 1.27 cm (0.5 in) centers. The particle size range of the limestone was from 1.68 mm (0.067 in.) to 1.0 mm (0.039 in.). The bed was pulsed with air by an electrically controlled solenoid valve, using the standard cycle of 2 seconds "on" and 3 seconds "off".

In the first phase, two 4-hr. runs were conducted at each of three flow rates: 4.54 lpm/m^2 (0.11 U.S. gpm/ft^2) 9.1 lpm/m^2

surface as would happen if slugging were occurring. A definite cause of the poor performance of the pilot scale limestone column with Brunswick No. 12 drainage could not be assigned, because of the effects of the various factors could not be separated without conducting further laboratory studies. These were not considered justifiable in view of the poor pilot plant performance. However, the experience showed the need for more comprehensive laboratory evaluation if limestone neutralization were to be considered for other minewaters.

Effluent Levels The analyses of the metal levels in the clarifier overflow (both extractable and dissolved) based on the three periods of operation, as well as on the overall run, are shown in Table 2-33. These results indicate that the clarifier overflow levels were independent not only on the height of the limestone column but also of the flowrate of the pulsing air, and the column feedrate. In addition, there was no difference in performance between a pulse cycle of 2 seconds on/3 seconds off and one of 1 second on/2 seconds off.

Table 2-34 presents the analyses of the effluent polishing results, both sand filtration and 24 hour bucket settled. Besides the results based on all the tests, sand filtration results were also analysed on the basis of the backwash used (Period 1 using a filtrate backwash, Period 2 using freshwater backwash) as indicated in Table 2-34. The analyses of the extractable metal levels in the clarifier overflow based on the different times during which the effluent polishing tests were performed are also shown in Table 2-34 for comparison purposes. Both polishing methods effectively reduced the clarifier effluent metal levels. No significant differences were noted between the results obtained by either technique. Sand filtration using freshwater backwash resulted in lower metal levels compared to operation with filtrate backwash. Filtrate backwashing resulted in gypsum precipitation in, and fouling of, the sand filters giving rise to poorer performance.

Sludge Characteristics Even though the sludge produced during this run contained some carbonate as a result of the initial limestone treatment, its characteristics would not be expected to differ too much from a sludge produced during lime only treatment since gypsum would be the

ferrous ion. The ratio of ferrous/total iron increased from 0.77 to 0.97 on passing through the limestone column reflecting the relative solubilities of the iron carbonates (or hydroxy-carbonate complexes) at the pH's encountered in the column.

An attempt was made to identify the factors responsible for the poorer-than-anticipated performance of the limestone column. Mechanical failures could not be blamed entirely, as poor results had occurred even when the actual operation of the column had been satisfactory. Three factors were considered to be primarily responsible: inadequate length of laboratory tests, differences between synthetic and actual minewater and scale-up effects (particularly, the reduced "slugging" effect and lower abrasion of the solids was obtained in the larger column). The use of a different limestone was not considered to be important, since both were classified as "high calcium". In laboratory tests, it was assumed that equilibrium had been reached when a constant effluent pH was achieved for 1 or 2 hours operation. However, this may not have been the true equilibrium. The synthetic minewater used in the laboratory tests contained very large concentrations of sulphates (17,000 mg/l) and sodium hydroxide, which had been added to raise the initial pH. Cursory measurements made during the laboratory trials indicated greater than 60 percent neutralization of acidity through the column at an effluent pH of 5.2 - 5.5. It is suspected that there was a significant difference between pH response and buffering capacity of the synthetic and of the real minewater. In the synthetic minewater, all the iron was in the ferrous form, whereas in the actual minewater a large portion of it was initially in the ferric state. Since studies have indicated that coating of the limestone is associated with the formation of ferric hydroxy complexes in the pH range 2 to 3, the actual minewater would be expected to coat the limestone more. The abrasion in the large column was likely inferior to that in the small one because of the absence of true slugging action. To achieve slugging, the bubble diameter must be at least as great as the column diameter. Although the actual movement of the limestone could not be seen in the large column, observation of the liquid surface above the limestone showed an upwelling in the centre of the column, rather than upward movement of the entire

+All metals are extractable values

Operation of the limestone column proved fairly straightforward. No difficulties were encountered in feeding, charging or cleaning the column. In addition, the bed showed no tendency to bind due to calcium sulphate precipitation as long as the unit was pulsed with air (rather than continuously air fed). For most of the run, a two second on, three second off air pulse at a rate of 707 lpm (25 cfm) was used; however, between January 25 to February 5 difficulties were encountered with the solenoid timing valve and air was fed continuously during this period.

Results

Limestone Column Analyses of the limestone column effluent parameters based on the entire run and on the periods of operation are given in Table 2-32. Metal analyses based on the entire run are given also. Overall, only about 22% of the acidity of the acid mine drainage was removed by the limestone column. Acidity removals for the three operational periods were 25%, 16% and 19% respectively. The actual height of the limestone column had little effect on acidity removal. The increase in acidity reduction over Period 1 was due at least in part to the recharging of the bed. A short period of poor performance during this period (due to timer problems) caused substantial deposition of iron hydroxide on the limestone and the reactor had to be recharged with fresh limestone. The removal of acidity by the limestone column was much less than anticipated.

The limestone column caused a decrease in the sulphate content of the influent. Mean influent sulphate values of 7,680 mg/l, 8,548 mg/l and 8,778 mg/l for the three operational periods decreased to corresponding effluent values of 7,395, 8,336 mg/l and 8,202 mg/l.

The limestone column also effected the removal from solution of heavy metals by precipitation. Based on mean dissolved values determined by the overall run, zinc, copper, total iron and lead removals were 1.5, 11.0, 34.0 and 61.0% by weight respectively. This trend in metals removal reflects the relative difficulty in removing the various heavy metals from solution in the pH range 4-6. The column also caused the precipitation of most of the ferric ion but little of Fe^{++}

Effect of changing pH on distribution of different CO_2 related ions in solution.

PEARSON, et al. (1982) present a theory on the decarbonation process and design procedures for CO_2 removal from limestone-treated mine wastewaters and provided equations and nomographs for the stripping of CO_2 from wastewater by air.

Freezing Points of Caustic Soda Solution

NAOH NEUTRALIZATION OF AMD

Use of NaOH for AMD treatment would normally not be considered economically attractive. NaOH, although consumed stoichiometrically, costs much more than lime. One advantage of NaOH, especially where solutions must be recycled many times, is that no gypsum builds up with its related scale problems.

For small installations which do not justify the capital cost of an HDS plant or even an agitated lime reactor, lime addition system, flocculant makeup system, thickener, etc., the much simpler equipment needed for NaOH addition may prove to be cost effective after all. The small additional cost of reagent will be more than justified by capital cost savings.

Three interesting applications of NaOH were observed for AMD treatment.

- Falconbridge Onaping Minewater, Ontario

Water pumped from the Onaping mine amounts to a small flowrate (about 103,000 Igpd or 470 m^3/d) but required neutralization nonetheless to precipitate dissolved nickel and to raise the pH high enough to precipitate nickel at pH10. The minewater, while the mine is in operation, runs pH 9-12. Because the volume is small and minor pH adjustment is only sometimes needed, this was achieved using a 50% NaOH solution metered directly from drums. Only 15 gpd was needed.

When the mine shut down temporarily, however, pH of AMD dropped back to 7 because cemented backfill was no longer being pumped underground, and the advantages of NaOH over lime were less apparent.

The neutralized minewater drains by gravity to a small settling pond fitted with a floating plastic boom curtain to increase the residence time. Metal hydroxides, mainly of nickel and iron, precipitated and sank to the bottom of this pond leaving a clear supernatant to discharge.

Two interesting phenomena should be taken into account. First, in cold conditions great care must be taken when using liquid NaOH solutions as they have very high freezing temperatures as shown on the following graph. 50% NaOH freezes around 54°F. The second phenomenon has to do with the discharge of sewage from the mine into this settling pond. Sludges settled to the bottom as well, where, because of warm conditions in summer in the shallow pond, bacterial action generated gases which attached themselves as minute bubbles to precipitate sludge particles on the floor of the pond. This occured to an extent that the sludges containing 6% Ni were floating to the surface and discharging to the greater lake water system. Not much of this precipitate needs to get into a water sample to get a very high reading.

More can be learned about this phenomenon from:

IN-LINE AERATON FOR ACID MINE DRAINAGE

The U.S. Bureau of Mines IN Pittsburgh, Pennsylvania, has developed a simple low capital cost device to treat AMD using NaOH as a neutralizing reagent. Their system is described by ACKMAN and KLEINMANN (1984).

The basis for the system is to use a jet pump to inject air and caustic soda into the system which subjects the water to be treated to instantaneous rapid pH change. After mixing in the jet pump, a static mixer is used. These flocs settle well to yield a normal sludge density of 2-3%.

Of interest is the fact that the precipitate settles as a green ferric hydroxide sludge which oxidizes as it ages to a red ferric hydroxide of a day or two.

One amazing feature is the behavior of manganese. When an AMD solution containing 70 ppm Mn was tested, about 50% of the Mn precipitated and settled at pH 4-5 and almost quantitatively at pH 7-9.

In the case of a West Virginia coal mine, AMD containing 900-1000 ppm Fe^{2+}, all the iron could not be precipitated at once, and two in-line systems were needed in series, each associated with a separate settling pond. Decant solutions meeting the regulatory discharge levels were very easily achieved.

The advantage of the in-line system is that it has no moving parts and is designed to fit on the end of the pipeline delivering the AMD from underground.

The system consists of a venturi jet pump with a mixing chamber and an internally spiralled static mixer. The small scale unit could achieve the same result as a conventional lime-aeration device costing over a million dollars.

Normally, solutions containing 500 ppm Fe^{2+} and 10-20 ppm Mn can be handled in one pass. One solution containing 70 ppm Mn was tested, and it achieved a 30 ppm Mn effluent in one pass. The portable unit was to be tested on more sites during the summer of 1984.

There is a fair degree of oxidation of Fe^{2+} to Fe^{3+} even without adding alkali to the system. For example one solution containing 20 ppm Fe^{2+} was treated at pH 5.5-6, and the iron in the ILS effluent was dropped to below 1 ppm without alkali addition.

Further tests are in progress using lime and pulverized limestone and by the 1985 Technology Transfer meeting anticipated by the AMD Group at the USBM Bruceton Laboratories; they hope to have design data.

Several design observations have been made:

- The higher the water pressure, the more air is drawn into the system.
- 20% caustic solution is a convenient way to add NaOH together with the air flow.
- A 4"Ø trash pump from suppliers like Homelite give only 20 psi and, using the jets alone without static mixer, only 14% of the iron was oxidized.
- Larger pumps are prefered as these give 40 psi, but without a static mixer, only 14-15% of the iron oxidizes.
- To accommodate larger flows, several jet pumps can be mounted in parallel.
- 1500 gpm has been handled through three jets in parallel. A maximum of 200 psi is recommended.

THE USBM ESTIMATES THAT OVER $1 MILLION/DAY IS SPENT BY THE MINING INDUSTRY ON ACID NEUTRALIZATION, AND OVER 5000 MILES OF STREAMS ARE ADVERSELY AFFECTED BY AMD THAT HAS NOT BEEN TREATED.

FEATURES OF THE IN-LINE AERATOR SYSTEM (ILS)

1) Simultaneous aeration and neutralization.
2) Extremely rapid oxidation of ferrous ions.
3) Low capital cost of equipment.
4) Low maintenance equipment.
5) Reduced space requirements.

Meanwhile, it is known that at least two companies are working on commercial applications of this sort for jet pumps.

A 6" aquaflow hydraulic submersible trash pump was used with some success in conjunction with the ILS test rig. These are available from among others:

MARK PLACE
Post Office Box 10926
Pittsburgh, PA 15236
(412) 892-2000

Feed to the pump should be screened to keep the ¼" holes in the jet from clogging.

A 12"Ø Helix or static mixer is used as supplied by Polcon Sales Ltd.

The system has been demonstrated at a flow rates of 300-1500 U.S. gpm.

Interesting pH phenomema have been observed. For example, pH could likely be at 6-9 at the exit point of the air jet but have dropped at the end of the day in the pond to pH 4-6. By the following day, pH in the pond has dropped further to pH 3-4. This no doubt is due to the oxidation of ferrous to ferric hydroxide in the precipitates.

The ILS treatment method has been tested and applied by the U.S. Bureau of Mines. One location where it is used is:

KITT ENERGY COMPANY
BCNR Mining Division
Meadowland, PA
(412) 228-8400
Tom Simonetti

The Bureau of Mines uses the Penberthy jet pump; the supplier's address is shown below:

The best source of design parameters for this system is:

John R. Ackerman

Barrett, Haentjens & Co. have developed an improved jet pump for turbulent mixing of dry reagents, water, and air in the same reactor placed in line with a pump.

The patented Turbojet system has multiple jacket chambers in the jet pump for mixing and multiple nozzles up to 24 or 48. The units are available in three sizes, the largest of which is priced at $16,000. They are made of 316 stainless steel.

The three sizes are:

100- 300 gpm
300- 600 gpm
600-1000 gpm

The 1000 gpm model aspirates 400 cfm air.

Barrett and Haentjens have tested, with satisfactory results, the use of dry lime and even limestone dust for direct application in the Turbojet to remove iron from AMD. They are now working on a dry lime delivery system.

The first commercial scale Turbojet system is being installed at SOHIO COAL CO.'s Guys Run coal preparation plant at Fairmont, West Virginia. It will use NaOH as reagent purchased dry and fed as a 20% solution.

Barrett, Haentjens and Co. are eager to combine the Turbojet and HDS processes and with their hydrorake sludge transport system.

MIXING WITH THE TURBOJETT

1556

HAZLETON TURBOJETT SYSTEMS*

The TURBOJETT System is a new and unique high intensity turbulent mixer. The TURBOJETT System can be effectively utilized to mix any combination of liquids, solids, and gases. Since the high intensity mixing is done efficiently, the cost of reagents is minimized. The TURBOJETT mixer is easily maintained and has no moving parts. TURBOJETT mixers incorporate all of the elements of a complete treatment process. An entire treatment system can be self-contained and portable.

Cross Section

There are many possible arrangements of the TURBOJETT internals. Based on the particular materials to be mixed, the feed components can be introduced at various locations in the jacket area or at the rear of the mixing chamber.

As an example, raw water feeds containing high concentrations of solids (slurries) are usually fed through the rear of the mixing chamber. In this case, chemical reagents would enter the mixer through the jacket area.

Annular jacket surrounding mixing chamber allows injection of air and water (or reagents) into mixing zone. The jacket can be divided into as many sections as required, based on application

TURBOJETT DESIGN FEATURES

Efficient

Field tests have demonstrated that a TURBOJETT System can meet or exceed the performance of higher cost, stationary mixers and aerators. TURBOJETT mixers effectively utilize chemical reagents when combined with a well controlled and monitored reagent feed system.

Portable

Since the TURBOJETT design requires no mixing or aeration tanks, a complete treatment system can easily be arranged on skids or trailers to be moved from one location to another. Systems can be electrically powered or engine driven.

Adaptable Design

Our engineers will "custom design" a total system to meet YOUR specific needs. Flows larger than 50 GPM can be processed economically. Flows ranging in thousands of GPM can be handled by larger and/or multiple mixers. Materials of construction are available to handle most acidic, alkaline, and/or abrasive mixtures. Designs can easily be up-graded to accommodate increased capacity at minimal cost. Mixer internal porting can be provided as separate, replaceable rings to accommodate changing flow rates or abrasive wear problems. Our engineers can advise you if the TURBOJETT can be retro-fitted to your present operation.

Easily Freeze-Protected

Requiring no reaction vessels, TURBOJETT Systems can be completely drained for freeze protection. Outdoor systems can be designed for intermittent, automatic operation in the coldest of climates.

Easily Maintained

A typical TURBOJETT mixer for 150 GPM is only five inches in diameter and seventeen inches long. It weighs a mere twenty pounds. These mixers are easily inspected, cleaned or replaced. Separate internal rings are available and can be replaced in minutes.

Reduction of Mineral Build-up Maintenance Problems

Many chemical reactions coat the surfaces of piping, mixers and aerators, and often render them completely inoperable. The TURBOJETT is well suited to these situations because of its easily maintained design. Spare nozzle rings or whole mixers can be replaced in minutes. The small size of the mixer lends itself to cleaning in an "acid bath" or similar cleaner.

In Line Treatment Capability

Complete treatment systems can be designed to eliminate open reaction vessels and aerators. Freezing effects of cold weather or the emission of toxic fumes can be avoided because the system is completely contained within a pipeline. Precise control can be achieved because system lag times are short.

Self-Contained Systems

A completely assembled, compact treatment system can be arranged for an engine drive. This flexibility makes the TURBOJETT System ideally suited for treating waters at remote locations. Government regulations for clean streams at remote outfalls can more readily be achieved.

Choice of Materials

TURBOJETT mixers can be provided in a variety of materials to meet your needs for corrosion or abrasion resistance. Our foundries cast over 50 different alloys and have been able to meet the requirements of the chemical, mining, paper, mineral processing and metals industry.

Automatic Control

The TURBOJETT System can be equipped with automatic controls which can continuously monitor the quality of treated water and adjust the reagent feed. Since the lag time between reagent addition and process control measurement is short, control is accurate.

TESTING

Barrett, Haentjens recognizes that each water treatment problem has its own peculiarities. As such, we offer complete field or pilot testing. While we do not guarantee that our system will successfully treat water in every situation, we offer a complete program for application testing. This allows you to determine how well the TURBOJETT System works in your situation. The approach eliminates any risk, since our design can be tested for each application.

Successful testing has been done under the direction of the U.S. Bureau of Mines in the area of acid mine drainage treatment. Testing in the area has successfully continued with several on-site tests at customer's facilities.

BUREAU OF MINES 1984

IN-LINE AERATION AND TREATMENT OF ACID MINE DRAINAGE

By T. E. Ackman[1] and R. L. P. Kleinmann[2]

ABSTRACT

The Bureau of Mines has invented a simple, low-maintenance system to mix and aerate mine water in a pipeline. It consists of a jet pump, which entrains air by Venturi action, and a static mixer, which induces turbulent flow. The system has no moving parts and is designed to use the pressure generated by an existing mine water discharge pump.

The in-line aeration system has been field-tested at a mine site in Greene County, PA, where high ferrous iron (Fe^{2+}) concentrations were causing discharge problems. Discharge concentrations of Fe^{2+} were reduced from 10 to 20 mg/L to 0.2 to 0.9 mg/L by installation of the aeration system. At high influent Fe^{2+} concentrations (47 to 240 mg/L), the system also proved effective, despite low pH conditions (4.6 to 5.6).

Neutralization and aeration were combined into a single step by injecting sodium hydroxide (NaOH) into the port of the jet pump. This resulted in oxidation of the Fe^{2+} within a few seconds, indicating that combining neutralization and aeration optimizes reaction rates.

INTRODUCTION

Acid mine drainage (AMD) results from the exposure and subsequent oxidation of sulfide minerals (primarily pyrite) associated with coal and adjacent strata. The acidic reaction products are dissolved by infiltrating rainwater, eventually emerging in acid seeps or springs. Many factors influence the quantity and quality of water handled by a mining operation, but it is not unusual for a single mine to treat 1 million gal of acid water a day. Costs of treatment range up to $500,000 per year, with the entire industry probably spending over $1 million per day.

Conventional AMD treatment consists of four steps: (1) neutralization, (2) aeration, (3) settling and disposal of sludge, and (4) effluent discharge. A flow diagram for a conventional AMD treatment plant is shown in figure 1. Capital costs for such a facility range between $500,000 and $2 million (1).[3] Most treatment plants use lime for neutralization, but NaOH and limestone (2-3) may also be used.

Aeration requirements vary, based upon iron concentrations and flow volume. Iron dissolved in the acidic water is often in the reduced Fe^{2+} state. Before discharge, that iron must be oxidized to Fe^{3+} so that it will hydrolyze and

[3]Underlined numbers in parentheses refer to items in the list of references at the end of this report.

FIGURE 1. - Standard AMD treatment process.

precipitate as $Fe(OH)_3$, commonly known as yellowboy. The rate of Fe^{2+} oxidation is a function of dissolved oxygen (D.O.) and pH:

$$\frac{-d\ [Fe^{+2},\ mol/L]}{dt} = k\ \frac{[Fe^{+2},\ mol/L] \times (D.O.,\ mg/L)}{[H^{+},\ mol/L]^2}, \tag{1}$$

where pH > 3.5, and $k = (1.25 \times 10^{-14})\ h^{-1}\ mg^{-1}\ mol^{-2}\ L^{+3}$, or

$$\frac{-d\ [Fe^{+2},\ mol/L]}{dt} = k\ [Fe^{+2},\ mol/L] \times (D.O.,\ mg/L), \tag{2}$$

where pH < 3.5, and $k = (1.57 \times 10^{-35})\ h^{-1}\ mg^{-1}\ L^{1}$.

Ferrous iron (Fe^{+2}) and H^{+} are given in mols per liter, whereas D.O. is given in milligrams per liter, and "k" is the rate constant obtained from the literature (4-6) and expressed in the appropriate units. Equations 1 and 2 can be integrated to yield relations for the amount of time ($t_{1/2}$) necessary for an initial Fe^{2+} concentration to decrease by 50 pct as a result of oxidation to Fe^{3+}, assuming constant pH and D.O., as follows:

$$t_{1/2} = \frac{(\ln 2) \times [H^{+},\ mol/L]^2}{k\ (D.O.,\ mg/L)}, \tag{3}$$

where pH > 3.5, and $k = (1.25 \times 10^{-14})\ h^{-1}\ mg^{-1}\ mol^{-2}\ L^{+3}$, or

$$t_{1/2} = \frac{(\ln 2)}{k\ (D.O.,\ mg/L)}, \tag{4}$$

where pH < 3.5, and $k = (1.57 \times 1^{-35})\ h^{-1}\ mg^{-1}\ L^{+1}$.

It is obvious from equations 1 and 3 that pH plays an extremely important role above a pH of 3.5 in reducing iron levels. As can be seen from equations 1 through 4, D.O. is also important. Even if aerated, mine water contains only about 8 to 10 mg/L D.O., which is consumed at the rate of 1 mg/L for every 7 mg/L Fe^{+2} oxidized.

To replenish the D.O., settling ponds or lagoons are constructed wide and shallow to maximize diffusion of oxygen into the water and thereby increase D.O. transfer from the atmosphere. However, oxygen diffusion is relatively slow (7), so that at many sites supplementary aeration sources are necessary. For example, diffusion can be increased by increasing turbulence. This is typically accomplished by incorporating a series of open-channel drops in the flow path of the water, which increases the D.O. concentration. Mechanical aerators can also be used to continuously introduce bubbles of air into the water. This continuous replenishment of D.O. is effective in maintaining a rapid reaction rate, but it also has disadvantages: A separate aeration tank or basin is required; there are high initial capital costs; and there are operating costs associated with power consumption and maintenance, especially where gypsum precipitation is a problem.

This report describes a Bureau-designed treatment system, currently in full-scale operation, which has proven to have economic and environmental advantages over conventional treatment. The In-Line Aeration and Treatment System, or more simply, the In-Line System (ILS), functions in existing AMD pipelines using the energy of existing mine water discharge pumps. It offers reduced maintenance, operating, and capital costs, as well as improved reaction time.

ACKNOWLEDGMENTS

The authors thank Kitt Energy Corp. and especially R. Kantzlieter, senior environmental engineer, and T. Simonetti, environmental engineer, for their cooperation and assistance. The authors also gratefully acknowledge the cooperation of Walter Sarsfield, mine inspector, Pennsylvania Department of Environmental Resources. Important technical assistance and interpretation of data were provided by engineering technicians R. Lipscomb and A. Woods and mining engineering technician J. Odoski, of the Bureau of Mines. Finally, a special thanks to Mark Place of John P. Place, Inc., who played a principal role in the conception and design of the ILS.

FIELD TEST

UNIT DESCRIPTION

The ILS consists of two off-the-shelf components: a jet pump (8) and a static mixer (fig. 2). Both components can be described as aeration and mixing devices. Jet pumps are simply nozzles that entrain air by Venturi action (fig. 3). The jet pump used was made of polyvinyl chloride (PVC). Water enters under pressure generated by the existing mine water discharge pump and is converted by the jet pump into a high-velocity stream. This stream then passes through a suction chamber, which is open to the atmosphere. If the system is being used for neutralization as well as aeration, the suction chamber also serves as the injection point for the neutralizing material (e.g., lime, NaOH or potassium hydroxide (KOH), or finely ground limestone). Alternatively, the neutralizing material can be mechanically injected into the line by a metering pump anywhere before the ILS. After passing through the jet pump, the flow enters the static mixer (fig. 4). The static mixer consists of 1-ft sections of pipe made of copolymer polypropylene resins, laminated together end to end with fiberglass. Inside each section is a 1-ft helix that forces the water to follow a spiral path. Helixes are used routinely in sewage and industrial waste water treatment plants as vertical airlift aeration and mixing units, but that design was modified somewhat for this horizontal application. Each helical unit was rotationally offset 90° from its neighbor, thereby interrupting the corkscrew every foot and enhancing the mixing action. Eight 1-ft sections were used, which provided the

FIGURE 2. - Schematic of in-line aeration and treatment system (ILS).

FIGURE 3. - Jet pump diagram.

FIGURE 4. - Static mixer diagram.

contact time of a normal 32-ft pipe because of the induced spiral flow.

AERATION FIELD TEST

The ILS was tested and is currently in operation at a remote site in Greene County, PA. Historically, the mine water discharge from this site required no treatment. However, early in 1982, water quality began to deteriorate. In April 1982, the mine operator asked the Bureau of Mines for technical assistance because iron concentrations at the discharge end of the mine water settling ponds were exceeding legal discharge limits. Bureau investigators analyzed the water entering the settling ponds from the underground mine and found that Fe^{2+} levels were erratic but often exceeded 100 mg/L. D.O. was measured at 7.2 to 8.0 mg/L from the discharge pipe at the surface. Given the estimated detention time of the two settling ponds (about 4 days) and the influent pH (6.2-6.6), equation 1 was used to determine that sufficient oxygen was not available for complete Fe^{2+} oxidation and that additional aeration was needed to increase the rate of reaction and allow time for the $Fe(OH)_3$ to settle. As an alternative to mechanical aeration, the ILS was installed at the end of the discharge pipe from the underground mine on May 14, 1982 (fig. 5). It would actually have been preferable to splice the ILS in further up the pipeline to provide additional contact time. However, the operation of the jet pump has limitations in terms of back pressure from the discharge side of the line.

Monitoring of the discharge from the pond began on the fourth day after installation of the ILS. Ferrous iron

FIGURE 5. - Schematic of test site.

concentrations dropped from 10 to 20 mg/L before installation of the ILS to 0.2 mg/L on May 20. Subsequent Fe^{2+} concentrations ranged from 0.2 to 0.9 mg/L. Total iron concentrations fell from over 20 mg/L to less than 2 mg/L.

However, raw water quality continued to worsen during the summer of 1982 because of reduced pumping at an adjoining mine. Total iron concentrations in the effluent ranged from 2.1 to 20.8 mg/L because of higher influent Fe^{2+} concentrations (up to 240 mg/L) and declining pH (as low as 4.5).

Faced with the necessity of neutralization and yet reluctant to construct a conventional AMD treatment plant, the mining company decided to inject NaOH into the mine waterline. This would allow them to quickly meet acidity and pH standards in the effluent and would also provide water of sufficiently high pH for efficient Fe^{2+} oxidation in the ILS.

Injection of the NaOH (KOH during winter) into the mine waterline proved to be more difficult than the mining company first envisioned. Variations in water quality and flow and problems with the feed pump resulted in inconsistent and inefficient neutralization. Although this caused problems for the mine operator, it allowed rates of iron oxidation to be evaluated over a wide range of pH, with and without the ILS. When the ILS was not being used, the pipe discharge was arranged to provide turbulent conditions for initial aeration as the water entered the pond. Data for this setup is presented in table 1. Water was collected at the pipe discharge and also 1 day later as it flowed from the first to the second pond. This 1-day detention time for the first pond is an approximation and was affected by the amount of sludge accumulated in the pond. Using the discharge of the pond allowed evaluation of data despite the fluctuating water quality. It is important to note that the values in table 1 do not represent site discharge concentrations.

TABLE 1. - Effect of pH on Fe^{2+} concentrations, in milligrams per liter, with turbulent flow aeration but without the ILS

pH[1]	After neutralization	After 1st pond (1 day later)
5.6.....	473	305.0
6.4.....	199	.8
6.5.....	332	71.0
6.5.....	208	.6
6.6.....	351	86.0
7.5.....	208	1.6
8.7.....	320	.1
9.5.....	12.5	.7

[1]The pH was measured before the water flowed into the first pond.

Table 1 demonstrates satisfactory Fe^{2+} oxidation at a pH of 7.5 and above but inconsistent Fe^{2+} oxidation at pH 6.6 and below. The extent of iron removal that is occurring indicates that D.O. is being replenished in the pond by diffusion from the atmosphere. Assuming a fully aerated system and an initial Fe^{2+} concentration of 100 mg/L, one can calculate the minimum time it should take to reduce iron concentrations to an average legal discharge value below 3.0 mg/L at any pH (table 2).

With the approximate 24-h detention time of the first pond, it would be

expected that most of the Fe^{2+} would be removed at pH 6.5 but that the amount oxidized would drop off rapidly below pH 6.5. With less D.O. present, as is the case in the pond, oxidation kinetics should be proportionally slower. The two occasions where Fe^{2+} oxidation remained efficient at pH 6.4-6.5 imply better aeration on these days, perhaps owing to weather conditions.

TABLE 2. - Time required to oxidize 97 pct of 100 mg/L Fe^{2+} at various constant pH's and constant oxygen saturation

pH	Time, h	pH	Time, h
4.5....	3.5×10^4	7.....	3.5×10^{-1}
5.....	3.5×10^3	7.5....	3.5×10^{-2}
5.5....	3.5×10^2	8.....	3.5×10^{-3}
6.....	3.5×10^1	8.5....	3.5×10^{-4}
6.5....	3.5		

Table 3 presents Fe^{2+} concentrations in the mine water when the ILS was used. Unfortunately, pH was lower during the time interval when the ILS was connected than earlier, but this only serves to emphasize that Fe^{2+} oxidation is occurring much faster than would be predicted.

TABLE 3. - Effect of ILS on Fe^{2+} concentrations, in milligrams per liter

pH	After neutralization	After ILS	After 1st pond (1 day later)
4.6..	185	188	4.1
5.3..	240	210	6.0
5.4..	55	52	5.5
5.5..	87	75	5.5
5.6..	141	141	11.0
5.6..	47	44	2.8

For example, at pH 5.5 and an initial Fe^{2+} concentration of 87 mg/L, a detention time of over 10 days should be required to reduce Fe^{2+} concentrations to 5.5 mg/L. Similarly, at pH 4.6 and an initial Fe^{2+} concentration of 185 mg/L, the detention requirements to reduce Fe^{2+} to 4.1 mg/L should exceed 400 days. Yet the Fe^{2+} is being oxidized, despite the low pH.

The mine water flows through the ILS in about 4 s and remains in an effervescent state for perhaps another minute before the bubbles disperse. From equation 3, it can be calculated that approximately half of an initial Fe^{2+} concentration would be oxidized in this short interval at pH 7.5 but only about 5 pct at pH 7.0. Below pH 7.0, the ILS unit is simply raising the D.O. level about 1 mg/L above what might be achieved with a turbulent discharge, which should account for the oxidation of only 5 to 10 mg/L of additional Fe^{2+}. Clearly the ILS is performing much better than would be expected.

The observed oxidation rates suggest that the ILS is either directly catalyzing the rate of iron oxidation in the pond or somehow creating a catalyst. Since turbulent discharge into the pond should mimic the direct effect of the ILS well, it seems that a catalyst is being created by the ILS. Tamura (9) demonstrates that amorphous ferric hydroxide catalyzes the oxidation of Fe^{2+}, at a rate that increases in proportion to available oxygen, surface area, and adsorption of Fe^{2+} on the $FeOH_3$, but decreases with pH. The crystalline phase associated with ferric hydroxide, lepidocrocite (γ-FeOOH), which consists of very small and very thin rectangular plates (5), has also been shown to catalyze Fe^{2+} oxidation (4-5), though again the effect diminishes with decreasing pH. It seems likely that the ILS must be increasing the rate of catalysis by $FeOH_3$ or γ-FeOOH by increasing the rate of particle formation, by altering the particle surface area, or by increasing the availability of oxygen.

IN-LINE NEUTRALIZATION AND AERATION

Because of the problems that the mine company was experiencing with injecting the NaOH into the pipeline, the Bureau suggested that the jet pumps of the ILS could also serve as an injection port. A pilot-scale test was conducted using a 55-gal drum of NaOH and a siphon hose, adjusting the feed rate by valve adjustment so that pH at the ILS discharge

averaged about 7. Four sets of water samples were collected at three points in the ILS: before the jet pumps, after the jet pumps, and after the static mixer. The average values from the test are listed in table 4.

TABLE 4. - Effect of simultaneous in-line neutralization and aeration on water quality during flow through the ILS--pilot-scale tests

Parameter[1]	Before treat-ment	After jet pumps	After static mixer
pH[2].....	4.5	6.7	6.9
Acidity or alkalinity[3]...mg/L..	-810	+45	+70
Ferrous iron...mg/L..	190	4.8	2.4
Total iron.....mg/L..	260	95	40

[1]All values are averages.
[2]Geometric averages (1).
[3]- indicates acidity; + indicates alkalinity.

Once again the Fe^{2+} iron is being oxidized much faster than would be predicted. Based on the average values shown in table 4 for pH and Fe^{2+}, very little Fe^{2+} should be oxidized during the 4 s of contact time in the ILS. Alternatively, one can look at the extent of Fe^{2+} oxidation and calculate that an apparent average pH of at least 8.5 must exist throughout the ILS, despite the measured pH. This apparent contradiction between anticipated and measured values is probably a result of the simultaneous aeration and neutralization. As the NaOH is injected, the instantaneous pH is extremely high (over 10) for a fraction of a second. For that instant, reaction rates are extremely fast, with a reaction halftime measured in microseconds and limited only by D.O., which is being continuously replenished by the jet pump.

If this hypothesis is correct, combining neutralization and aeration should consistently result in high Fe^{2+} oxidation rates. The point of injection for the NaOH was moved to the jet pump port, and samples were collected on randomly selected days over a 2-month period. The oxidation of Fe^{2+} was even more rapid than was observed earlier in the pilot-scale test (table 5). Iron levels in the discharge from the second pond consistently met regulatory requirements for site discharges. In many cases, virtually all of the iron was oxidized after passage through the ILS; on some days, the jet pump alone was sufficient to reduce Fe^{2+} to below detectable limits. This efficiency is attributed to the higher pH's in the system, which in turn reflects the fact that injection of NaOH no longer poses the problem that it did earlier.

TABLE 5. - Effect of simultaneous in-line neutralization and aeration on water quality during flow through the ILS--full-scale operation, Fe^{2+} iron concentration in milligrams per liter

pH after static mixer	Before treat-ment	After jet pumps	After static mixer	After 1st pond

COST ANALYSIS

The total capital cost of the ILS was less than $3,000. Operating costs, based on an estimated 10 pct additional power consumption by the mine discharge pump, is about $800 per year. By way of comparison, a mechanical aerator sized for this site would cost $10,000 to $20,000, with an estimated operating cost of about $2,200 per year.

Since the ILS lacks moving parts, maintenance is much simpler for this system than for a mechanical aerator. Icing, a problem sometimes associated with spray

from the mechanical aerator, should not pose a problem with the ILS; and gypsum scale, if it develops, can be dislodged simply by striking the ILS unit.

If the ILS is incorporated in a new AMD plant, space can be conserved by designing ponds that are deeper than normal, since diffusion of oxygen into the pond is no longer essential. This will allow detention requirements to be based solely on settling requirements. Increased pond depths can also reduce pond cleaning frequency, or alternatively, extend the life of a pond used for sludge disposal.

CONCLUSION

The ILS is a simple and inexpensive approach to aeration of mine water. It significantly increased oxidation rates above theoretical limits through the mixing and aeration action of the jet pump and static mixer. At a pH of 5.5, oxidation rates were 10 times faster than anticipated; at pH 4.6, oxidation rates were over 400 times faster than anticipated.

The rate of Fe^{+2} oxidation was further accelerated by incorporating neutralization into the ILS. When NaOH was injected into the injection port of the jet pump, the simultaneous aeration and neutralization maximized the Fe^{+2} oxidation reaction rates, so that almost all of the Fe^{2+} was oxidized as the water flowed through the ILS. The extremely high rate of Fe^{+2} oxidation observed can probably be attributed to the extremely high instantaneous pH in a portion of the flow, which reduced the reaction halftime ($t_{1/2}$) in that portion to microseconds.

The ILS is much more economical than conventional mixing and aeration devices. The total capital cost of the system, at this particular site, was less than $3,000--about one fifth of the price of a conventional aerator. Operating and maintenance costs for the ILS are also much lower than for the conventional mechanical aerator.

J. David Holm

The Wannamaker Continuous Concentrator was invented by:

W. W. (BILL) WANNAMAKER
Post Office Box 1121
Camden, SC 29020
(800) 845-2202

A partner in the development of the Continuous Concentrator is:

COLORADO MINERAL AND CHEMICAL CO. LTD.
2885 Mount Herman Road
Monument, CO 80132
(303) 481-3710
George M. Morris

The intention of Mr. Wannamaker and Mr. Morris is not to manufacture and market the Continuous Concentrator as an item of equipment but rather to offer their services, including their knowledge of the design, testing, and operation of the technology, to solve difficult solid-liquid separation and other process problems. They indicate that the equipment can be designed also to operate up to nearly 1000°F also under high pressure, and that it is most effective for removal of particle sizes of 1-10 microns for crystalline solids removal from water.

REMOVAL OF TRACE ELEMENTS AND ACIDITY FROM THE ARGO MINE TUNNEL DRAINAGE

BY

J. DAVID HOLM

DONALD H. SIMPSON

April 1981

Historic Features of Drainage From the Argo Tunnel[1]

The Argo Gold Mill, for years a part of the State Historical Society of Colorado Inventory of Historical Sites, has been nominated to the National Register for inclusion on the National Register for Historic Places.

The mines of Clear Creek and Gilpin were famous but so were many of the problems in mining these areas. Water was seeping into the workings at such a rate that pumps were working 24 hours a day. Ventilation was a serious problem. Finally, transportation of men and the ore they mucked along shafts approaching 1,000 feet in vertical lift was getting far too expensive.

The idea of tunneling into a mountain to reach ore on a slightly inclined plane was not new when it was first applied to mining in the Rockies. During the late 1870's, many miners and speculators started tunneling operations. The Argo Tunnel was one of the few that succeeded.

Incorporating the Argo, Drainage, Transportation and Tunnel Company in 1893, Sammuel Newhouse started a project to intersect the productive ore bodies between Idaho Springs and Central City and provide economic transportation for bringing ore to the surface, drainage for the mine workings and ventilation to the miners.

No one took Newhouse's tunnel very seriously until around 1895 when the Argo started serving as a drainage system for several mines. By February 1896, the tunnel had been driven one mile into the mountain toward Central City. In 1898 the Argo Tunnel had reached a length of 7,000 feet, had intersected 200 mines and over 1,140 veins.

By 1904 the tunnel had been driven 12,000 feet and was serving many mines, including a number of operations that Newhouse had personally acquired. The mines were producing gold, silver, lead, copper and iron sulfides (in demand as a flux by the smelters for a period of time).

During these years, practically all of the mines in the western portion of Gilpin County were having serious drainage problems except for those connected into the Argo. Unfortunately, however, the Argo never successfully negotiated payment for this service from many of the major mines and the stockholders in the Argo lost this revenue.

The Gem, Sun and Moon, Saratoga, Poco, Ophir, Old Town, California, Gunnell, Prize, Gregory-Buell, King Bee, Kansas-Burroughs, Waluga and Bi-Metallic were some of the major mines serviced from 1905 to 1943. Production of precious metals from these mines is estimated to total more than $100 million at old values. Much of this production was a direct result of the Argo.

The Argo Gold Mill became a part of the operation in 1913, three years after the tunnel to Central City was completed at a final length of 21,968 feet.

As is true of the history of most mining operations, the Argo Tunnel and Mill have had a sporadic history of operations, with years of activity followed by years of idleness. This pattern was stopped permanently on January 19, 1943, when blasting on a lateral to the Kansas shaft broke loose a great volume of water which immediately flooded the Argo Tunnel. Four men were killed and the tunnel was closed, as was the flow of ore to the Argo Gold Mill.

Several less serious "blow outs" of toxic mine water occurred during the past 25 years. These voluminous releases of polluted water are believed to be caused by roof collapses in the tunnel which prevent water from draining normally. Instead, water backs up behind these "dams" and tremendous hydrostatic pressures can develop. On May 21, 1980, a near catastrophic release of toxic water occurred which resulted in the temporary shutdown of 5 downstream municipal and industrial water intakes. Clear Creek was severely impacted throughout the entire downstream reach 35 miles to the confluence with the South Platte River.

Characteristics of Drainage from the Argo Tunnel

The Argo Tunnel (formerly the Newhouse Tunnel) is 21,968 feet or 4.16 miles long and intersects about 26 ore veins. The principal geologic formations in the vicinity of the tunnel are Precambrian schist, gneiss and granite. Fractures in these rock types results in their porosity. Construction of the tunnel was undertaken to intersect the largest veins in the Idaho Springs - Central City area at greater depth than the deepest shaft workings. The tunnel decreased mining costs, provided cheap transportation of the ore to the mill and railroad at Idaho Springs, and provided a means for draining the workings. Drainage was a major consideration leading to the construction of the tunnel. Lakes who noted in 1900 that "The arrival of the tunnel at or rather beneath the mines will be an enormous help to (the miners) especially in getting rid of the water with which they are at present overburdened."[2] The drainage currently that "One mine (in the Central City area) for years raised on an average 40 tons (36 t) of water for every ton of ore and rock." The drainage currently enters Clear Creek several hundred feet from the tunnel entrance.

Previous Water Quality Studies

Moran and Wentz (1974) studied the Argo Tunnel drainage in 1973. Two samples were collected - one on January 24th and one on June 28th. The field-measured pH was a 2.8 on January 24th and 2.6 on June 28th, a relatively insignificant difference. Calcium and magnesium concentrations also were very similar on the two dates; however, most dissolved (9.45-micron-membrane-filtered) and total concentrations of cadmium, cobalt, copper, iron, lead, manganese, nickle, silver, and zinc showed a net increase of 1.4 to 2.7 times between January and June. Dissolved cobalt and dissolved lead increased 4.4 and 6.7 times, respectively. Except for cobalt and lead in January, iron in June, and silver at both times, all trace elements were almost completely dissolved (88 percent or greater).[3]

The Argo Tunnel was next studied by Bovles, Cain, Alley, and Klusman (1974) from May 17 through September 28, 1973. They noted no change in flow (1.2 ft^3/s or 0.034 m^3/s) from the tunnel during the period July 3rd to August 16th, and stated that the flow averaged 1.2 ft^3s (0.034 m^3/s) during the period June 25th to August 31st.[4]

Concentrations of dissolved cadmium, copper, iron, manganese, zinc, and sulfate in the drainage on May 17th were higher than during the rest of the study period. Variations in concentrations fo these parameters from June 29th through September 28th were relatively insignificant. The pH varied only from 2.6 to 2.8 for the entire period of May 17th through September 28th. The analytical methods and quality-control procedures used have been endorsed by the U.S. Geological Survey.

Wildeman, Cain, and Ramiriz (1974) published analyses for three samples from the Argo Tunnel for the period October 30, 1973, through February 8, 1974, and found no dramatic changes in major or trace-element concentrations. They used the same analytical methods and quality-control procedures as Boyles, Cain, Alley, and Klusman (1974). Although Wildeman, Cain, and Ramiriz (1974) did not filter their water samples, it has been shwon previously that most trace elements in the drainage are primarily in the dissolved state (p.24).

The definitive study of the quality of water draining from the Argo Mine portal was done in a 1977 study conducted by Dennis Wentz of the U.S.G.S., entitled Mine Drainage Study for the Metropolitan Denver and South Platte River and Tributaries Report (1977). Samples collected over a one year period between 1976 and 1977 were analyzed for a complete suite of chemical parameters. The Argo mine drainage was found to flow at a fairly constant rate of .3 cfs and to contain extremely high concentrations of dissolved salts and toxic heavy metals. Of particular concern in the raw mine drainage are As, Cd, Cu, Fe, Mn, Pb and Zn. Each of these parameters exceed proposed water quality standards for Clear Creek (the receiving stream by at least an order of magnitude). The chemical results of that study are summarized below in Table 1.[5]

The Colorado Mined Land Reclamation Division, Inactive Mine Program conducted a mine drainage impact evaluation project from May 21, 1980 to November 18, 1980. The Argo Mine drainage was sampled on 5 occasions during that period. The first samples obtained on May 21, 1980 were taken almost immediately after a voluminous blow out of mine water was released from the tunnel. Large flows in the range of 4 cfs drained from the tunnel for a period of weeks after the blow out. By June 11, the flows had ebbed to 1.5 cfs and in November a flow of .6 cfs was registered. There is excellent agreement between the chemical sampling results provided by Wentz (1977) and those provided by McLaughlin Industrial Waste Engineers for the Inactive Mine Program. Table 2 presents the later sampling results.

TABLE 1: U.S.G.S. Mine Drainage Study (1977)[1]

Summary of Physical and Chemical Data for the Argo Mine Drainage

Parameter	Concentration Range mg/l	Mean mg/l Concentration	Proposed Water Quality Standard mg/l

1. Sampling period Mar. 11, 1976 to Mar. 18, 1977. 14 samples collected & analyzed for each papameter.
2. Exceeds proposed water quality standard.
3. Sampling period May 21 - Nov. 18, 1980. 5 samples collected & analyzed.

Acid Mine Drainage

The production of acid mine drainage occurs when iron sulfides (Pyrite and Marcasite) are oxidized in the presence of water. The interaction of water, air and sulfides produces ferric hydroxide, sulfate and acidity. This oxidation process would not manifest itself if the pyrite were left in its naturally reducing environment. During mining operations, pyrites may be exposed to air and underground workings or above ground in open pits, overburden piles, and tailings piles. Regardless of the location, acid is formed if the pyrite comes in contact with oxygen and water.

Acid is formed in a series of inter-related reactions:

1. Pyrite, (chemical name ferrous sulfide), when exposed to water and air oxidizes to form ferrous (Fe^{+2}) sulfate and sulfuric acid.

2. The ferrous sulfate can then be oxidized by either more air exposure or by bacterial activity to form ferric (Fe^{+3}) sulfate.

3. The ferric sulfate can then contribute further to acid formation in two ways. First it can serve as an oxidizing agent, oxidizing additional sulfides. The sulfur released by this reaction serves as an energy source for a species of acid producing bacteria (thiobacillus thiooxidans). Secondly, the ferric sulfate can be hydrolyzed to form ferric hydroxide and additional sulfuric acid.

Separately or in combination, chemical or bacterial oxidation of pyrites produces acid water. Four equivalents of acid are produced during theis cycle, two during oxidation of sulfide and the remaining two with the resulting hydrolysis of ferric iron.

Increased acidity in turn lowers water pH and can place large concentrations of metal ions in solution. This is especially true for drainage from metal mining districts such as those found in the Rocky Mountains of Colorado. Generally, metal mine drainage has low pH and high metal concentrations. The mobility of these metal ions under natural conditions appears to follow the sequence below:

Most mobile Mn Zn Cu Cd Fe Ni Pb Least Mobile

These metals can be toxic to aquatic life even in small concentrations. In addition, these metals can make water unsuitable for domestic or industrial uses. In Colorado, most of the problems associated with acid mine drainage are found in the mountains where underground mines have been established. Ground water flows through mine workings and picks up acidity as well as dissolved metals. Spoil piles and tailings pollute surface drainage as well.

Acid Mine Drainage Control Methods

Various methods exist for controlling acid mine drainage. They are generally divided into at-source abatement and drainage treatment. At-source abatement refers to techniques used to reduce water contact with sulfide material or to keep acid mine drainage away from streams. Drainage treatment consists of chemical and/or physical means of improving drainage water quality after it has been impacted. Different techniques can be used for surface or groundwater conditions.

A. At-Source Abatement

These techniques are usually preferred for control of acid mine drainage. At-source abatement generally consists of physical structures that require little or no maintenance. In cases where spoils or tailings affect water quality, the following control methods are presented generally in order of increasing cost.

Soil Cover and/or Revegetation

Vegetative cover stabilizes waste piles, reduces erosion and slows surface runoff. However, some plant species increase infiltration and thus may increase acid mine drainage production. Use of soil to cover tailings reduces infiltraiton and provides stabilization. Soil also allows for easier establishment of vegetation. The drawbacks to using soil and vegetation cover involve acquiring the needed soil and seed, transporting this material to an alpine site and having success to the site.

Rerouting Drainage & Water Handling

Diversion of water around tailing piles is another method used to reduce acid mine drainage. This approach is less expensive and perhaps more effective than soil cover and revegetation. One problem is the maintenance of proper channel slope and hydraulic regime. In addition, rainfall can still percolate though spoil material.

Channel Lining

The placement of impermeable material, such as clay, along a channel bottom is another way to reduce water flow into tailings. This method can also be used in conjunction with rerouting.

Spoil Treatment

The placement of impermeable material on top of spoil or the addition of chemicals to spoil for reduction of infiltration through the spoils. Chemical treatment is also used. The long term effectiveness of these types of treatments isquestionable. They are also expensive, especially when dealing with remote sites.

Mine Sealing (Flooding)

Closure and sealing of inactive mines is one way to eliminate acid mine drainage. Flooding of underground mines reduces the oxidation of sulfides and does not allow free drainage. However, the potential exists for the development of large hydrostatic heads. These large heads could rupture the mine seals or force water to be discharged through fracture systems and thus negate the objective. These drawbacks preclude the use of this control technique especially for metal mines in mountainous areas.

Air Sealing

Air sealing is a control measure used to limit the amount of oxygen available to underground workings. Reduction of oxygen leads to a reduction in acid mine drainage produced. This technique would not work well in tunnels that drain extensive workings where air could enter through numerous ventilation shafts.

Time Discharge

This technique can be used with either mine seals or settling ponds. The objective is to store acid mine drainage until high stream flows when it can be assimilated with fewer impacts. The drawbacks to this approach include, design of large enough impoundments, potential for water rights conflict and limited benefits to the stream.

Residence Time Reduction

The less time water is in contact with sulfidic material, the fewer metal ions can be dissolved. Rapid drainage of underground workings by removal of obstructions and lining of channels may reduce metal concentrations in mine drainage. This technique has not, to date, been adequately tested but may yield significant results.

B. Treatment of Acid Mine Drainag

Treatment of acid mine drainage refers to chemical and physical procedures used to improve mine drainage quality. In general, these measures require continual maintenance to be effective. Thus, these measures are implemented only in extreme cases where such water quality improvements are justified.

Alkali Neutralization Followed by Settling or Filtration[6]

Alkali neutralization is the most widely used chemical treatment of acid mine drainage. The addition of alkali material increases pH and causes the precipitation of many metal cations as insoluable hydroxides or carbonates. Several alkali materials are available for use, these include Quick lime, Hydrated lime, limestone, Dolomite, Magnesite, Caustic Soda, Soda Ash and Ammonium Hydroxide. These materials are composed of sodium or calcium, hydroxides or carbonates. All of these agents form a "sludge" when used in the neutralization process. Disposal of this sludge is a major problem.

Several shortcomings are apparent with the use of hydrated lime (calcium hydroxide) and Quick lime (calcium oxide). These compounds can increase hardness and cause gypsum ($Ca\ So_4\ .2\ OH$) to form scaling. In addition, overtreating can occur causing high pH values in the treated water.

The use of Limestone, Dolomite or Magnesite also has serious drawbacks. In the presence of Iron, Iron hydroxide precipitates onto the reaction surfaces of the rock fragments and coates them. Some form of "reactor" is needed to remove the iron coatings and keep the reaction surfaces fresh. When iron is present the pH is limited to about 6.5 due to the formation of carbonic acid. The reaction rate for limestone etc. is dependent upon rock fragment size.

Reverse Osmosis[7]

The process of reverse osmosis involves inducing movement of water from a high solute concentration to a low solute concentration through a membrane filter by the application of pressure. A highly concentrated brine is formed on one side of the filter and clean water on the other side.

Generally, suspended solids must be removed from the water prior to treatment so they will not foul the membrane. High sulfate concentrations in the water to be processed can cause formation of calcium sulfate which can also foul membrances. The pH of the water produced is low and must be treated to reach discharge standards. Disposal of the accumulated brine is another problem. However, this method has been effective for removal of trace metals.

One proposed method for treating brine water is by the use of alkali neutralization. However, the problem of sludge disposal is still present.

Ion Exchange[8]

Ion exchange involves the chemical substitution of a more desirable ion for the less desirable pollutants. A home water softener is an ion exchange unit that exchanges sodium (salt) ions for calcium and magnesium (hardness) ions. Ion exchange is the interchange of ions between a solid medium (resin) and and aqueous solution. Two columns are usually set up, one to remove anions, the other for cations. Mineral contrations in the water produced. Several varieties of ion exchange units have been developed. They differ primarily in the resins used and ions removed. Generally, these units do not remove enough of each ion to meet discharge standards.

Note: Neither reverse osmosis or ion exchange is particularly well suited to the extreme concentrations of severely polluted AMD. Although they will work on the worst water, the practicality of such applications is low.

Electrodialysis

Electrodialysis is similar in principle to reverse osmosis except that electric potential is the driving force instead of pressure. Two membrances bound each cell, one filters anions, the other cations. Ferric iron has been found to foul membranes and must be removed prior to treatment.

Underground Injection of Trace Elements

This method for reducing acid drainage involves injection of an alkali slurry into underground mines. The alkali slurry would be used to neutralize mine drainage before it reached the surface. In addition, a precipitate would form which over time would seal off the mine and stop drainage.

One obvious drawback would be the possibility of failure in the precipitated seal could cause flooding of nearby areas. This is especially true for metal mines in mountainous areas where large heads could develop behind the seal. Another drawback would be the depletion of alkali material over time. The amount of neutralization obtained through this procedure is difficult to determine.

Treatment Costs[9]

Reliable cost figures are difficult to obtain from the literature. Most costs quoted are paper-study costs developed from feasibility studies. A range of reported costs will be presented in Table 3 for the purposes of discussion. It must be emphasized that actual costs depend on a very large number of variables such as plant size, type of equipment, degree of sophistication, water quality, costs of reagents, waste disposal, costs of labor, etc. In reality, these figures mean very little to the specific situation.

TABLE 3: Estimated Range of Costs for Treatment

Method	Estimated Cost Range, dollars/1000 gal.
Lime neutralization	0.20 to 1.30
Limestone neutralization	0.15 to 1.00
Soda ash neutralization	0.40 to 3.00
Sodium hydroxide neutralization	0.50 to 3.50
Reverse osmosis treatment	1.00 to 5.00
Ion exchange treatment	1.00 to 7.00

Neutralization, Precipitate Concentration, and Filtration of Argo Mine Drainage

Neutralization of acid mine drainage is a proven and cost effective method for removing trace elements from solution. However, many of the flocs (precipitates) that form during neutralization reactions are quite light in weight and tend to remain suspended rather than settling out. It is always more difficult in treatment situations to remove the precipitates from suspension than it is to increase the pH, oxidize the trace elements and precipitate them in the first place.

Oftentimes, settling basins or clarifiers are used to separate the flocs from the liquid-solid suspensions created during the neutralization process. It is a problem to make this separation before the slurry reaches the outlet of the settling pond or clarifier. Short circuiting is almost always a problem with settling ponds. Instead of using the entire volume of the basin for settling, only a narrow path from the inlet to the outlet is used. Sometimes baffles are installed in the pond to enhance its suspended solid removal efficiency. In many cases coagulants (chemicals to improve settling) are used to remove suspended solids.

Unfortunately, there is not sufficient land area between the portal of the Argo Mine and Clear Creek, the receiving stream, to allow construction of a settling pond. Filtration systems are also used to remove precipitated solids from solutions. However, most filtration systems remove solids from slurries, which means all of the solids must be removed to obtain a clear liquid. Also, filtration equipment such as the labor intensive plate and frame filter press or the continuous rotary vacuum filter remove solids with a relatively low moisture content. Such filtration systems do achieve their purpose but with high costs and considerable inflexibility.

It is more desirable to remove clear liquid from the suspended solids in the slurry on a continuous basis resulting in variable levels of moisture content in the sludge. In this way the amount of clear water recovered becomes inversely proportioned to the moisture content permitted to remain in the sludge. For this type of filtration, a concentration device is necessary which pumps neutralized slurry through a filter system capable of retaining micron sized particles in the slurry while producing high clarity filtrate. This type of concentration is done most efficiently by passing the slurry through the filter system a number of times and extracting water on a continuous basis. This requires a lower pressure drop for filtration than the common types of equipment which rely on a single pass of the slurry through the filter system with a high pressure drop. Of course multipass filtration of slurries can concentrate the sludge only to the point that the thixotropic nature of the material allows it to be pumped. Where a high percentage of water recovery is desired it is best to concentrate in several stages using separate concentrator modules.

A precipitate concentration and filtration device was tested at the Argo Mine Tunnel. The system used was a Wannamaker Continuous Concentrator furnished by Colorado Minerals & Chemicals Ltd. with a capacity of 57,600 gpd product flow.

This particular continuous concentrator apparatus is a relatively simple device designed to fractionally remove solids from liquid-solid suspensions or slurrys. The continuous concentrator is essentially portable and employs a modular design so that a wide range of flows can be treated. The system uses relatively little floor space and was installed inside a building near the portal of the Argo Mine Tunnel.

The device was used simply to remove minerals from mine water using a precipitation and filtration process. A schematic of the continuous concentrator apparatus is presented in Figure 1.

Continuous Concentrator System Evaluation

Sampling of the effluent from the continuous concentrator water treatment/minerals recovery system at the Argo Tunnel was performed on October 15, 1980. The test unit was operated as a single stage multipass concentrator with an intermittent feed of raw mine water and a continuous product flow of clear effluent water. The concentrated sludge was discharged from the tank following the experiment. The sludge has not yet been assayed for mineral content.

Samples of processed water or effluent were taken as the system was operated at various pH values. The objective of the sampling program was to determine the optimum pH range which provided maximum precipitation of dissolved metals in the Argo Mine drainage and produced an effluent of acceptable quality. Approximately 450 gallons of raw water draining from the Argo Mine Tunnel was pumped into the concentration consolidation tank and sampled for pH and baseline metal concentrations. Industrial Grade Caustic Soda (NaOH) was then added to the tank in measured increments until the pH of the mine water was raised to 11.5. The mine water and sodium hydroxide were thoroughly mixed using the centrifugal pump and a return line to the consolidation tank. After complete mixing this water was then pumped into the continuous concentrator and the system was operated for 5 minutes and allowed to reach equilibrium. An effluent sample was obtained and analyzed for pH and metal concentrations.

The system was operated continuously and effluent samples were obtained at pH 11.5, 10.5, 9.8, 8.3, 7.2, 6.6, 6.0 and 5.6. The pH was lowered gradually by simply adding raw mine water to the consolidation tank (which had originally been spiked with NaOH). At each desired pH level the system was allowed to equilibrate prior to extracting effluent samples. The pH of all effluent samples was measured immediately with a pH meter. All samples were acidified with HNO_3 and analyzed on an atomic absorption spectrophotometer by the Industrial Laboratories Company. The following parameters were analyzed: Total dissolved solids, sulfate, sodium, arsenic, cadmium, chromium^{+3}, chromium^{+6}, copper, iron, manganese, lead and zinc. The results of the examination of the effect of increasing pH on removal of trace elements from the Argo Mine drainage using the continuous concentrator system are presented below.

WANNAMAKER CONTINUOUS CONCENTRATOR

Effluent Sampling Results

Samples of effluent from the continuous concentrator apparatus were analyzed over nearly the entire pH range. Concentrations of dissolved solids (TDS) specific salts such as sodium and sulfate, and numerous trace metals were determined for each sample. The sample results yield information about the optimum pH value where maximum metal precipitation occurs and accordingly, the best effluent quality is achieved. The results obtained are presented in tabular form in Table 4. The same results are presented graphically in Figure 2.

Although the metals analyzed theoretically precipitate over a large range of pH values, sampling results show that most metals reach their lowest effluent concentration in the range between pH 7 and pH 9. Co-precipitation and other interactions must occur in acid mine drainage in order to produce the results observed. Lead and copper seem to precipitate out of solution in the low end of this range and zinc and cadmium drop out at the high end near pH 9. When the system is operating in the optimal range from the standpoint of removing metal from solution, lead, cadmium, manganese and sulfate remain elevated above proposed water quality standards.

The excessive lead and manganese levels do not present major water quality concerns, since the numeric standards for these parameters are directed at protecting water supplies. The Argo drainage, of course, is not a water supply. Rather, Clear Creek which receives the drainage from the Argo mine is the water supply. The continuous concentrator operating at pH 7.2 reduces lead loading to Clear Creek from .140 mg/l in the raw untreated drainage to .02 mg/l. Lead levels of .02 mg/l are not considered toxic to aquatic life. The first water supply intake below the Argo discharge is some 15 miles downstream just above the town of Golden, Colorado.

The Manganese standard is also set to protect water supplies from undesirable staining effects. Manganese is not considered toxic at the levels discharged by the continuous concentrator system operating between pH 7 and 9.

Cadmium levels in the effluent drop from .29 mg/l in the raw untreated drainage to .004 mg/l when the system is operating at pH 9.2. The proposed water quality standard for cadmium to protect aquatic life is .002 mg/l. The slightly elevated concentration of cadmium that would be discharged by the system might create a weak chemical barrier for certain aquatic species in the mixing zone of the Argo drainage and Clear Creek.

Sulfate does not appear to be affected significantly by the operation of the continuous concentrator system. Sulfate is of concern in water supplies for livestock and people. Clear Creek is used for these proposes currently notwithstanding the discharge from the Argo Mine.

When the continuous concentrator is operated at pH levels lower than 8.3, some trace metal concentrations increase beyond the point considered toxic for aquatic life. Of course, sodium concentrations continue to drop as water within the system is diluted with raw mine water in order to lower the pH. Sodium levels are elevated in effluent from the system since sodium hydroxide is used as the neutralizing agent.

The results of the sampling program indicate that the range providing optimal treatment of the Argo Mine drainage using the continuous concentrator apparatus falls between pH 8.3 and pH 9. Below pH 8.3 metal concentrations in the effluent rise above fish toxic levels. Above pH 9, excessive alkalinity produces toxic effects on aquatic species. While the concentration of sodium in effluent within this optimal pH range is slightly excessive, the tremendous dilution effect afforded by Clear Creek which is the receiving stream, would eliminate any potential impacts to agricultural users. There are no standards for sodium in Clear Creek under the recently proposed standards for the South Plattee Basin.

TABLE 4: Chemical Quality of Effluent when Operating the Continuous Concentrator System with Variable pH.

Parameter mg/l	pH 3.4	6.6	7.2	8.3	9.2	9.8	10.5	11.5	Proposed Water Quality Std. mg/l

Conclusions

1. The treatment process of neutralization, precipitate concentration and filtration is effective for reducing trace element levels from the Argo Mine drainage. When the pH of the mine water in the system is raised using NaOH, the concentrations of metal in the effluent are observed to drop radically. The dissolved metals react with the NaOH to form insoluble metal hydroxide compounds which immediately precipitate out of solution. When the slurry of mine water and metal precipitates is pumped into the continuous concentrator, the suspended solids are retained within the system and returned to the consolidation tank. Meanwhile, clear effluent is discharged from the concentrator system.

2. The optimum pH range for operating the continuous concentration system is from 8.3-9.0. The system, operating in this pH range produces a clear colorless effluent from the Argo Mine drainage which meets all applicable water quality standards except those for cadmium, lead, sulfate and perhaps manganese. Cadmium concentrations in the effluent only slightly exceed the cold water aquatic life standards set for Clear Creek for the reach below the Argo Tunnel. Lead concentrations in the effluent would be acceptable for cold water aquatic species but exceed drinking water standards. The first intake for a potable supply is some 15 miles below the Argo Tunnel. The extremely high sulfate concentrations in the Argo drainage are largely unaffected by the treatment system.

3. The treatment process evaluated in this study produces a sludge product composed of metal oxide and metal hydroxide compounds. Whether these metal compounds are individually separable and recoverable was not analyzed in the study. If the oxidized metals are indeed separable and recoverable, markets do exist for the products derived from the sludge produced in the sodium hydroxide neutralization reaction.

4. The operational and maintenance costs as well as equipment costs for the neutralization, precipitate concentration and filtration process evaluated in this study probably fall in the mid range of estimated costs for common acid mine drainage treatment systems (see Table 3). However, if the sludge product is marketable, treatment costs may be reduced or eliminated.

Recommendations

1. Test the neutralization and continuous concentration system on a number of other acid mine drainages in Colorado to assess its effectiveness in removing trace elements from waters having various chemical qualities.

2. Test the neutralization and continuous concentration system handling small, medium and large in-flow volumes.

3. Analyze the sludge products from the neutralization and continuous concentration system. Determine the separability and recoverability of oxidized metals in the sludge. Evaluate potential markets for sludge products.

APPENDIX A

Toxicity of Trace Elements

The toxicity of trace metals in humans is a complex subject that is dependent upon many factors. In a multi-ion solution, as found in nature, the individual metal ions react, which can cause changes in toxicities compared to a single ion solution. One ion may block the toxicity of another ion. This is known as an antagonistic effect. Two ions can also work together increasing the toxicity of either one alone. This is known as a symergistic effect.

Toxic effects are also a function of the valance state of the element. One particular valence state may be more toxic than another. Also an element may or may not demonstrate antagonistic or synergistic effects or even toxicity based upon its valence state.

Toxicity is also dependent upon an elements interaction with the human body. Some elements (metals) are accumulated in the body and are never released. Thus small concentrations introduced over a long period of time may be harmful. Other elements pass through the human body and never build up. Certain elements, such as Mercury, accumulate not only in humans but in other animals as well. Consumption of these other animals leads to concentration of these elements further up the food chain.

The following is a list of the recognized toxic trace metals found in surface water. The descriptions for each metal includes available information on average intake as well as lethal doses. U.S. Public Health Service (USPHS) levels for drinking water are also presented.

Arsenic

In the trivalent state arsenic can be extremely toxic to humans. It accumulates in body tissue over time, thus small doses can be harmful. Average human intake is approximately 0.9 mg/day. USPHS and Colorado Drinking Water Standards call for .05 mg/l maximum concentrations.

Arsenic may occur in water as a result of mineral dissolution, industrial discharges, or the application of insecticides. Severe poisoning can arise from the ingestion of as little as 100 mg arsenic; chronic effects can appear from its accumulation in the body at low intake levels. Carcinogenic properties have also been imputed to arsenic.

Cadmium

Cadmium has been shown to be toxic to man when ingested or inhaled. Exposure by the former route causes symptoms resembling food poisoning. Biologically, cadmium is a nonessential, nonbeneficial element recognized to be of high toxic potential.

Cadmium is accumulated in the liver and kidneys. A safe intake is considered to be in the range of 55-77 mg/day. USPHS and Colorado drinking water standards recommend levels of .01 mg/l and .002 mg/l to protect aquatic life. Cadmium may function in or may be an etiological factor for various pathological processes including testicular tumors, renal dysfunction, hypertension, arteriosclerosis, growth inhibition, chronic diseases of old age, and cancer.

Chromium

Hexavalent chromium is the more toxic species. However, chromium III is also considered toxic in large quantities. Above the 5 mg/l level chromium begins to concentrate in body tissues. USPHS drinking water standards call for chromium levels of less than .05 mg/l.

Copper

Copper is an essential trace element for the propagation of plants and performs vital functions in several enzymes and a major role in the synthesis of chlorophyll. A shortage of copper in soil may lead to chlorosis which is characterized by the yellowing of plant leaves.

The toxicity of copper to aquatic life is dependent on the alkalinity or hardness of the water because the copper ion is complexed by the anions present in the water, thereby affecting its toxicity. At lower alkalinity or hardness values, copper may be more toxic to aquatic life. Relatively high concentrations may be tolerated by adult fish for short periods of time, but the critical effect of copper appears to be its higher toxicity to the very young or juvenile fish.

Generally not a problem in natural waters, copper may cause a problem in regards to taste or aquatic life in industrial areas or where it is used as an alglicide or for slime control.

Iron

Iron is the fourth most abundant, by weight, of the elements that make up the earth's crust. Common in many rocks it is an important component of many soils, especially the clay soils where usually it is a major constituent. Iron in water may be present in varying quantities dependent upon the geology of the area and other chemical components of the waterway.

Iron is an essential trace element required by both plants and animals. Iron is an essential trace element required by both plants and animals. Iron is an objectional constituent in water supplies for either domestic or industrial use. The iron criterion in water is to prevent objectionable tastes or laundry staining (0.3 mg/l) constitutes only a small fraction of the iron normally consumed and is of aesthetic rather than toxicological significance. In an iron polluted Colorado stream, neither trout nor other fish was found until the waters were diluted or the iron had precipitated to effect a concentration of less than 1.0 mg/l even though other water quality constituents measured were suitable for the presence of trout. Some groundwaters and acid surface drainage may contain considerably more iron than this.

Lead

Lead is a very toxic element that accumulates in human tissues. Very small concentrations over a long time period can be detrimental. An average dose of lead is approximately 240-320 mg/day. Six hundred mg/day may be harmful to the human body. The World Health Organization recommends not more than .05 mg/kg body weight weekly. The toxicity of lead in water, like that of other heavy metals, is affected by pH, hardness, organic materials and the presence of other metals. Lead enters the aquatic environment through mine drainage, precipitation, lead dust fallout, erosion and leaching of soil, municipal and industrial waste discharges, and the runoff of fallout deposits from streets and other surfaces. In drinking water lead should be kept to a minimum; USPHS and Colorado water standards are set at .050 mg/1.

As far as is known, lead has no beneficial or desirable nutritional effects. Lead is a toxic metal that tends to accumulate in the bones of man and other animals. Although seldom seen in the adult population, irreversible damage to the brain is a frequent result of lead intoxication in children.

Manganese

Although rarely present in excess of 1 mg/1, manganese imparts objectionable and tenacious stains to laundry and plumbing fixtures. The low manganese limits imposed on an acceptable water stem from these, rather than toxicological, consideratons. Special means of removal are often necessary, such as chemical precipitation, pH adjustment, aeration, superchlorination, and the use of special ion-exchange materials. Manganese occurs in domestic wastewater, industrial effluents, and receiving streams, but is generally unimportant except as it may enter a potable supply intake.

Selenim

Selenium has a toxic effect on man and animals comparable with that of arsenic, giving rise to similar symptoms. Selenium also has been suspected of causing dental caries in man and of being a carcinogenic agent. Selenium poisoning is usually related to ingestion of food rather than water. It is widely used in industry and is naturally abundant in some soils.

The selenium concentration of most drinking waters is less than 10 ug/1. Concentrations exceeding 500 ug/1 are rare and limited to seepage from seleniferous soils. The sudden appearance of selenium in a water supply might indicate industrial pollution.

Sodium

Sodium ranks sixth among the elements in order of abundance; therefore, it is present in most natural waters. The levels may vary from negligible to appreciable. Relatively high concentrations may be found in brines and hard waters softened by the sodim exchange process. The ratio of sodium to total cations is important in agriculture and human pathology. Soil permeability has been harmed by a high sodium ratio. The alkali hazard involved in the use of a water for irrigation is determiend by the absolute and relative concentrations of the cations. If the proportion of sodium is high, the alkali hazard is high; and, conversely, if calcium and magnesium predominate, the hazard is low.

"Hard water makes soft land and soft water makes hard land." Alkali solids are formed by accumulation of exchangeable sodium and are often characterized by poor tilth and low permeability.

Zinc

Zinc is an essential and beneficial element in body growth. However, concentrations of zinc in water above 5 mg/l can cause a bitter astringent taste and a milky irridescence in alkaline waters. Zinc enters the waterway from mine related drainage, sewage discharges, and by the deterioration of galvanized iron. Zinc may also result from industrial waste pollution.

Zinc is considered toxic to aquatic species at far lower levels than for humans. In low hardness water levels as low as .100 mg/l are toxic to trout. Zinc and copper have a synergistic toxic effect upon cold water aquatic species (i.e. when combined in solution each is toxic at lower levels).

PASSIVE MINE DRAINAGE TREATMENT

Promoting Natural Removal Mechanisms for Acidity and Trace Metals from Mine Drainage

J. David Holm, Colorado Department of Natural Resources, Division of Mined Land Reclamation

Michael B. Bishop, Kaman Tempo

ABSTRACT

The most severe mining-related impacts upon water quality in Colorado arise from inactive and abandoned metal mines. This is partly because a mechanism for regulation and control of drainage from inactive mines has not been developed, and no cost efficient techniques for treating inactive mine discharges are available. There is, in most cases, no responsible entity to charge with the task of controlling discharges from such mines. In Colorado, Twenty five watersheds and 450 stream miles have been rendered barren of aquatic life and unfit for other beneficial uses as a result of toxic drainage from inactive mines. There is a great need in this state and throughout the nation for easy-to-construct, at-source treatment systems which effectively reduce acidity and metals concentrations and which do not require significant external electrical or chemical inputs for operation and maintenance. The term "passive mine drainage treatment" is used to describe the entire range of mine drainage abatement techniques which when combined or applied singly address this need. Passive treatment techniques can rely on natural geochemical mechanisms such as neutralization, oxidation, dilution, adsorbtion, and preciptiation, as well as techniques which involve physical intercession into the process of formation of acid mine drainage. This investigation focuses on the description of naturally occurring geochemical processes which have been effective in reducing metal concentrations and acidity at several sites in Colorado and the application of these same mechanisms in a passive treatment design for the Marshall #5 coal mine drainage problem area.

INTRODUCTION

Mine Drainage in Colorado

The most profound and widespread mine-related impacts to streams in Colorado are attributable to inactive and abandoned metal mines. More than 10,000 inactive metal mines exist in the state. These range in size from small prospecting holes to large-scale operations which have literally perforated entire mountainsides. Of course, not all inactive metal mines are significant contributors of stream pollutants.

Twenty-five watersheds and approximately 450 miles of stream are drastically impacted by metal mine drainage in Colorado (Wentz, 1974, Holm, et al 1982). The major sources of pollutant loading (i.e. mine dumps, discharges from adits, mill tailings etc.) within several of these drainages have been identified (Woodling 1976,1977; Davis et.al.1977; Holm, et. al.1979, Holm et.al.,1982; Kepler 1980; Carley, et. al.1981).

Because western coal deposits have low sulfur content, acid mine drainage is not usually a problem at abandoned coal mines. There are perhaps a half dozen examples of metal-laden acidic discharges from coal mines in this state.

Most of the metal mining in Colorado has occurred within a region commonly known as the Colorado Mineral Belt. Most metal mines within this region are located at high altitudes which, in terms of water pollution control and land reclamation, present some unique problems.

Drainage from inactive mines presents the most difficult point source category for which to develop control strategies. Many of the problem areas are located in rugged mountainous terrain which have limited access, especially in winter months. Access problems limit the choice of pollution abatement solutions to those which require little or no routine inspection or maintenance. Each inactive mine drainage problem is unique because of such features as the location of the mine, characteristics of the mineral body, the mining techniques used, and the hydrology of the area. Control techniques for mine drainage are highly dependent on these variables. Actual treatment options for a site cannot be determined until these characteristics are well defined.

The Colorado Department of Health, Water Quality Control Division currently lacks the resources and in many cases the authority to control water pollution from abandoned or inactive mines. The ownership of surface and mineral rights are often held by different parties. It is not uncommon that the present owners were not the operators during active mining but acquired the rights subsequent to mine shutdown. Since the original mining generally was done in a legal manner the liability of past operators and owners is in question. It would be difficult to assign responsibility to present landowners in most cases because of the high costs of reclamation work and small resultant land improvement benefits (Holm,1978).

Passive Mine Drainage Treatment

Given the difficulties of controlling pollution from inactive and abandoned mines in Colorado, there is a great need for mine drainage abatement and control measures which 1) effectively reduce pollution at the source; 2) require minimal heavy construction equipment for installation; 3) do not require significant electrical or chemical inputs to be effective, and 4) require infrequent inspection and maintenance activities. The term "passive mine drainage treatment" is used to describe the various techniques which may be used to reduce pollution from streams given these constraints.

Passive treatment refers in part to the reliance upon natural

geochemical processes for acid neutralization and metals removal. Poor access conditions dictate that only light construction work be required for initial system installation. Given the remoteness of most mines, operation of the treatment system cannot depend upon external power sources and frequent maintenance requirements. The present concept of passive mine drainage treatment utilizes the geochemical mechanisms of neutralization, oxidation, dilution, adsoprtion (cation exchange), co-precipitation, and precipition in order to reduce metals concentrations and acidity in mine drainage. Passive mine drainage treatments must be designed on a site-by-site basis to better incorporate local conditions which can enhance the natural geochemical processes required for treatment and to compensate for unique problems related to access, elevation, surface hydrology, type of mining and specific pollutants. Passive treatment approaches do not eliminate the need for detailed hydrologic evaluations and careful system design work. Rather, such treatment approaches require more rigorous evaluations and "front-end" planning and design. The success of passive mine drainage treatment approaches depend on the application of natural geochemical processes and the reduplication or simulation of naturally occuring metal and acidity removal systems. The goal of passive treatment systems is to reduce pollution to the maximum extent possible. Nearly complete removal of toxicants is possible with active treatment systems (Holm et.al.,1981).

The concept of passive drainage treament is mainly derived from observations of several natural systems in Colorado, where polluted mine drainage flows, in one case, into a small network of beaver ponds (Shuster Mine), and, in another case, into an artificial bog/pond (Delaware Mine). In both examples a significant reduction in heavy metal concentrations and acidity is realized within a very short drainage segment. These observations have been duplicated in bench scale experiments and field trials (Lapako et.al.,1981). Field scale investigations of the feasibility of using a passive mine drainage treatment system at the Marshall #5 coal mine are currently underway.

GEOCHEMICAL PROCESSES AFFECTING ACID MINE DRAINAGE

pH

The solubility of most elements and the stability of their compounds is extremely sensitive to the pH of the aqueous environment. The pH at which these elements precipitate as hydroxides is known as the pH of hydrolysis.

pH explains one mechanism by which trace elements are dissolved and transported in mine drainage or accumulate in stream sediments.
Mine water whose pH is below 4.5 commonly involves oxidation of some form of sulfur, usually sulfides. During the oxidation of sulfide minerals, pH decreases and high acidity values are generated. In this environment many metals are mobile. Mobility is decreased as the pH becomes higher (more alkaline).As acid mine water is diluted with waters of high pH, or as the acid waters react with rocks over which they are passing, the pH of these waters will tend to increase, and trace metals will precipitate out as their pH of hydrolysis is reached. The pH of mine drainage can increase in highly oxidizing conditions as well.

Eh - Oxidation/Reduction Potential

A measure of the oxidizing and reducing tendency of a solution is known by the synonymous terms Eh, redox potential, oxidation potential, and oxidation-reduction potential. The redox potential determines in large part whether many elements remain in solution or precipitate. When iron and magnanese are in a reduced state, that is as Fe^{+2} and Mn^{+2}, they are mobile in most natural enviornments. However, as soon as they are oxidized to the +3 and +4 states, respectively, their mobilities are greatly reduced and they are likely to form precipitates of iron and manganese oxides. In other words, the valence state determines in large part whether these elements remain in solution or precipitate. This is an example of the importance of oxidation-reduction processes.

In addition to abundant oxygen, free drainage is required for oxidation to be a significant process. Redox potential in many ways is analogous to pH. It measures the ability of an environment to supply electrons to an oxidizing agent, or to take up electrons from a reducing agent, just as the pH of an environment measures its ability to supply protons (hydrogen ions) to a base or to take up protons from an acid. The oxidation potential (Eh) is actually a measure of the voltage involved in the addition or removal of electrons during the change of the valence state of various elements (e.g., Fe, Mn, Cu). The energy required to change valence states is modified by pH. Therefore, both Eh and pH determine the concentration of an ion that will remain in solution, and a change in either may be sufficient to cause precipitation. The factors which govern the mobility or deposition of most heavy metal compounds can be summarized as: (1) oxidizing conditions promote precipitation whereas reducing conditions promote solution and, (2) acidic solutions generally promote solution whereas alkaline solutions promote precipitation.

Adsorption by Iron and Manganese Oxides

The hydrous iron and manganese oxides are of particular importance in mine drainage for two reasons. First, during their precipitation, they may incorporate, by coprecipitation, other elements which would normally be unaffected by changes in pH and Eh. Second, once formed, they have the tendency to adsorb (scavenge) elements with which they come in contact. (For this discussion, the term adsorption includes sorption, and is defined as the adhesion of ions or molecules to the surfaces of solid bodies with which they are in contact). The net result of both processes is that many metals, such as zinc and copper, which are normally very mobile, at least in slightly acidic solutions tend to become concentrated in the iron and manganese precipitates (Levinson,1980)

Adsorption (or desorption) of heavy metals such as Mn, Fe, Co, Ni, Cu and Zn occurs in response to the following factors: (1) instream concentration of Fe and Mn; (2) aqueous concentration of other heavy metals; (3) pH; and (4) amount and strength of organic chelates and inorganic complex ions present in the solution, (Levinson 1980).

Adsorption By Organic Matter

Organic (humus) layers in bogs or in soil can accumulate great concentrations of certain metals. In fact, the exchange capacity of humus can be as high as 500 meq/100g compared with clays which rarely exceed 150 meq/100g. Organic matter in swamps and bogs often shows high metal value. However, all metals are not adsorbed equally by organic matter. pH, Eh, and the nature of decaying material are probably important factors which influence adsorption.

The degree of enrichment of elements in the humus layers of bogs depends very largely on the type of aquatic vegetation, since plants vary greatly in their capacity to accumulate various elements. In many natural cases up to 90% of the bog mass is sphagnum, or peat composed of sphagnum remains. Sphagnum establishes itself in a thick, floating mat of sod across the bog. For metal adsorbancy, sphagnum is the next best thing to a sponge. Also peat adsorbs elements about as well as sphagnum (Krouskoff 1967).

The Shuster Mine Drain: A Natural Bog/Pond Treatment System

The Shuster Mine drains polluted mine water into Oak Creek, a tributary of the Yampa River. This mine opening is very near the town of Oak Creek. The town of Oak Creek is located along Oak Creek, approximately 20 miles southwest of Steamboat Springs, Colorado and 180 miles northwest of Denver.

Mining activity in the Oak Creek study area has been connected primarily with the extraction of coal. The coal in the area is bituminous and is associated with the Mesaverde group, which is composed of sandstone and shale of Cretaceous age. Copper has been reported in the district, but the nature of its occurrence is not known (Vanderwilt, 1947).

The Shuster mine drainage contains large concentrations of iron [8 mg/l], manganese [1.7 mg/l], cadmium [15 ug/l], lead [200 ug/l], zinc [40 ug/l]. However, these elevated levels of metals are not observed in Oak Creek even though the Shuster mine drains voluminous quantities of water (.1-9.0 cfs) relative to the flow of Oak Creek (Carley et.al.,1981).

Oak Creek, below the Shuster Mine drainge only exceeded water quality standards for zinc in the spring of 1980, and then it appeared to be caused by a background source. Zinc concentration gradually increased going downstream, independent from the Shuster mine drainage. Cadmium exceeded the water quality standards for Oak Creek in the spring and the fall, but in both cases exceeded the standards for these parameters above the Shuster mine, as well as below. Cadmium levels were only slightly influenced, if at all, by the mine drainage. Lead exceeded the water quality standards for Oak Creek in the spring above and below the Shuster Mine, but with no apparent effect from the mine drainage itself. The pH values for the Shuster drainage range from 5.9 to 7.7. Iron and Manganese were only slightly elevated in Oak Creek below the mine drain (Carley et.al.,1981).

The impact of the Shuster mine on Oak Creek is relatively minor, even though the mine drainage is somewhat spectacular to look at, showing graphic evidence of red staining. A natural phenomenon is occurring at this site which is somewhat remarkable. Mine water is cascaded down the face of the exposed sandstone outcrop below the adit resulting in oxygenation to the point of saturation. Beavers in the area have constructed several ponds and a rather elaborate system of canals and diversions below the Shuster adit. The net result is that the heavily oxidized Shuster drainage filters through the bog-like beaver dams and the effluent is gradually blended with stream water, until finally it joins the main stem. According to local Oak Creek residents, fishing in Oak Creek is about as good above Shuster as below.

Delaware Mine: An Artificial Bog/Pond Treatment Experiment

One of the first experiments in Colorado with metal mine draingage treatment using an artificial pond and bog was done for the Delaware (Blue Magazine) mine in the Peru Creek Drainage (Holm, et. al., 1979). Peru Creek is located just west of the continental divide and drains the west flank of 14,000 feet Greys and Torrey's peaks in Summit county. The Peru Creek area has been mined extensively for silver and other base metals in the last 110 years, with much of the mining having been initiated around 1870 and slowing considerably with the Silver Panic of 1892. For this reason, the sources of acid mine drainage and heavy metals loading are numerous and widespread.

The metal deposits that caused the big rush are predominantly complex ore, a mixture of copper, lead, zinc, and silver sulfide and native gold. One of the significant point sources of acidity and heavy metal loading to Peru Creek is the Delaware mine.

The mine is located on the east side of Cinnamon Gulch, which drains into Peru Creek. The portal is blocked, but effluent flows out through the rubble. There is a yellowish-orange (Fe) precipitate coating the drainage channels. On august 3rd, 1978, the effluent from the Delaware mine was re-routed into a small, heavily sodded pond that had been built before this time. The effluent was previously flowing across a large area of mine waste. Later samples were taken above and below this pond, to analyze the effectiveness of the structure in improving water quality.

Test results (Table 1) from the pond/bog experiment indicated that greater than 75% reduction in total metals loading concentration was achieved just by settling out the suspended solid and through adsorption of disolved metals onto the bog and soil materials in the pond.

Table 1

Delaware Mine Metal Loading (g/day)
above and below pond (Holm et. al., 1979)

	Flow (cfs)	pH	Cd	Cu	Pb	Zn	Fe	Mn
Mine drainage above pond	.33	3.9	1.2	9.0	2.0	343.	525.	277.
Mine drainage below pond	.31	4.5	0.3	2.0	0.1	72.	6.	49.
% reduction in metals loading (g/day)	---	---	75%	78%	95%	80%	99%	83%

Marshall #5 Coal Mine: Passive Treatment by Design

The Marshall #5 coal mine is located one half mile south of the town of Marshall and 4 miles south of Boulder, Colorado. This mine is one of the few inactive coal mines in Colorado which discharges a significant amount of metaliferrous acidic mine water. The water drains out across a portion of the Boulder City Open Space Lands.

This site has good potential for applying passive treatment principles patterned after the natural treatment systems described earlier. For water quality treatment the system is separated into two stages. The firxst stage of the treatment process involves oxidation and precipitation. Oxidation of the mine effluent is enhanced by creating very turbulent flows. Turbulance is induced by placing groins (rock gabions) in the channel. Fe and Mn are readily preciptated in oxidizing conditions. Other metals, are coprecipitated with the oxides of Fe and Mn. The pH of the drainage also tends to increase in heavily oxidizing conditions. Increasing pH allows further precipitation and coprecipitation.

This first stage of the process is further designed to encourage precipitation as the drainage passes through short sections of limestone cobbles which are placed in trenches periodically between the turbulance groins.

The second stage of the process involves small rock check dams, composed of durable limestone which are designed to temporarily detain the mine drainage and allow it to filter through heavy organic peat and living bog plant materials. The initial design concern was to select a suitable structure that would hold a deposit of peat materials and yet allow percolation of mine effluent through the peat materials.

The U.S. Forest Service has developed design criteria for low cost rock check dams that have provided a successful means of controlling gulleys in arid/semiarid regions of the west (Heed, 1966). The rock check dams are ideally suited to the construction of an artificial peat bog because of their ease of construction, durability, readily

available materials (loose rock) and the ability of the structure to feely pass water. The rock check dams not only serve as the structure to hold the peat moss but also tend to further aerate the acid waters.

In the case of the Marshall #5 treatment system, the key design elements to be considered are aimed at providing a stable, highly permeable rock structure that contains sufficient storage for a simulated peat and moss bog. For a loose rock structure of this type it is important to key the dam into the stream bed and stream banks. This measure prevents flow from eroding around the structure. Heede (1966) tested several dam configurations and found that loose rock dams should not exceed 6 feet in height. Therefore, the peat storage volume available behind the dam is dictated by the cross section of the stream. Since no upland watershed affects the flow of the mine drainage the appropriate spacing between dams is only influenced by the upstream extent of the peat moss in relation to the toe of the next upstream structure. Two structures have been designed for the Marshall #5 drainage. It is also considered important to provide rock aprons and similar bank protection below each structure to prevent undercutting, as well as, a properly designed spillway over each of the rock check dams.

The check dams function as retention devices to store plant materials and peat which are capable of adsorbing heavy metal contaminents. This simulated bog is composed of cured peat wood chips and hydrophilic acidophilic aquatic vegetation (Table 2). The shoreline of the loose rock impoundments is heavily revegetated with plant materials capable of metal uptake and which can tolerate acidic conditions . In time hopefully the organic litter from this vegetation will recharge the adsorptive capacity of the bog system.

Table 2

Bog Community Species to be Included in Simulated Bog at Marshall #5 Coal Mine (Hutnik et.al.,1973; Vallantine, 1971; Weber, 1976)

Aquatic Species	Terrestrial Species with High Water Tolerance	
Spnagnum Moss	Grasses:	Red-top
Water Hyacinth		Tall Wheatgrass
Pondweed		Western Wheatgrass
Horned Pondweed		Basin Wildrye
Frogbit		Tall Fescue
		Weeping Lovegrass
		Birdsfoot trefoil
Riparian Species	Forbes:	Strawberry Clover
Broad-Leaved Cat-tail		White Sweetclover
Field Horsetail		
	Trees:	European Black Alder
		Gray Birch
		Black Locust

Two other important features have been added to the design of the rock check dams to better faciliate metal adsorption (cation exchange) with the impounded peat materials. These design elements serve to facilitate flow of water through the peat materials and through the rock structures. A rock sub-drain is placed under the peat moss and a light gravel cover is placed over the peat moss. These features allow drainage through the lower portion of the peat moss and serve to hold the peat in place.

The loose rock check dam is designed to enhance metal adsorbtion and cation exchange. The result is a low cost, low maintainence artificial peat bog which filters the mine effluent.

Conclusion

The serious problem of acid mine drainage affecting water resources in Colorado is exacerbated by the fact that water is in such short supply. An arid state like Colorado, cannot afford to allow entire watersheds to remain incapable of sustaining beneficial uses because of the toxicity and aesthetic problems attributable to acid mine drainage. On the other hand, active mechanical treatment systems for hundreds of significant point sources of toxic mine effluent cannot be constructed, because of the huge amount of capitol this would require and the fact that this approach is not always appropriate for particular mine drainage problem areas.

Passive mine drainage treatment techniques are being developed which utilize and enhance natural geochemical processes for acid neutralization and metals removal. Such techniques rarely provide for total removal of toxicants from mine drainage. However, by accellerating the processes of oxidation, precipitation and adsorbtion, passive treatment techniques can provide significant reductions in pollution and decrease the overall length of impacted stream segments. The efficacy of passive treatment techniques is demonstrated from observations of natural systems and bench scale experiments(Lapako et.al.,1981). These observations and expermental results have been incorperated into the design of a passive mine drainage treatment system for the Marshall #5 coal mine.

ACKNOWLEGEMENTS

The authors gratefully acknowledge the conceptual and editorial assistance provided by Gerald L. Zimpfer, staff geohydrologist. with the Mined Land Reclamation Division. Valuable information about bog ecology and the prospects of revegetating the rock check dam impoundment areas with hydrophilic and acidophilic plant materials was provided by Thomas D. Gillis, Michael S. Savage, and Michael B. Long also of the Mined Land Reclamation Division..

ABSTRACT

The most severe mining-related impacts upon water quality in Colorado arise from inactive and abandoned metal mines. This is partly because a mechanism for regulation and control of drainage from inactives mines has not been developed, and no cost efficient techniques for treating inactive mine discharges are available. There is, in most cases, no responsible entity to charge with the task of controlling discharges from such mines. In Colorado, 25 watersheds and 450 stream-miles have been rendered barren of aquatic life and unfit for other beneficial uses as a result of toxic drainage from inactive mines. There is a great need in this state and throughout the nation for easy-to-construct, at-source treatment systems which effectively reduce acidity and metals concentrations and which do not require significant external electrical or chemical inputs for operation and maintenance. The term "passive mine drainage treatment" is used to describe the entire range of mine drainage abatement techniques which when combined or applied singly address this need. Passive treatment techniques can rely on natural geochemical mechanisms such as neutralization, oxidation, dilution, adsorbtion, and precipitation, as well as techniques which involve physical intercession into the process of formation of acid mine drainage. This investigation focuses on the description of naturally occurring geochemical processes which have been effective in reducing metal concentrations and acidity at several sites in Colorado and the application of these same mechanisms in a passive treatment design for the Marshall #5 coal mine drainage problem area.

I. Introduction

Mine drainage, particularly from inactive metal mines presents the most difficult point source of pollution to control and abate in the State of Colorado. Many mine drainage problem areas are located in rugged mountainous terrain which have limited access, especially in winter months. Access problems limit the choice of pollution abatement solutions to those which require little or no routine inspection or maintenance. Each inactive mine drainage problem is unique because of such features as the location of the mine, characteristics of the mineral body, the mining techniques used, the topography, and the hydrology of the area.

Given the difficulties of controlling pollution from inactive and abandoned mines in Colorado, there is a great need for mine drainage abatement and control measures which 1) effectively reduce pollution at the source; 2) require minimal heavy construction equipment for installation; 3) do not require significant electrical or chemical inputs to be effective, and 4) require infrequent inspection and maintenance activities. The term "passive mine drainage treatment" is used to describe the various techniques which may be used to reduce pollution from mine discharge given these constraints. The primary objectives of passive treatment systems for acid mine drainage are to increase the effluent pH and to obtain the maximum possible reduction in concentrations of dissolved heavy metals. Natural geochemical processes such as pH modulation and neutralization, aeration , dilution, cation exchange and adsorption, sorption and co-precipitation are relied upon to achieve these objectives at the effluent source (1).

Basic components of a passive treatment system include an ion exchange medium, limestone barriers or energy dissipators and cascades or waterfalls. An organic ion exchange medium (such as a peat bog) can be used to extract metals from the drainage, limestone is used to neutralize acidity, and waterfalls or gabions provide aeration and carbon dioxide exsolution, increasing the dissolved oxygen in the effluent and helping to raise pH.

Passive mine drainage treatment systems are designed on a site-by-site basis to be well adapted to local environmental conditions. Site specific treatments are required to compensate for unique problems related to access, elevation, surface hydrology, specific pollutants, type of mining and legal restrictions such as water rights and land use controls. While passive treatment approaches minimize the need for ongoing maintenance, they do not eliminate the need for detailed hydrologic evaluations and careful system design work. Such treatment approaches require rigorous site evaluations and "front-end" planning and design. The success of passive mine drainage treatment approaches depend on the application of techniques which emulate and enhance naturally occurring metal and acidity removal processes. The efficiency of passive treatment systems is determined in general by three major factors: the chemical processes involved in the formation of acid mine drainage, the natural geochemical processes applied in the components of a passive treatment system, and engineering and legal constraints.

II. Chemical Processes in Acid Mine Drainage

Formation of Acid Mine Drainage

The formation of acid mine drainage and the chemistry of the resultant solution following its discharge from the mine is extremely complex. However, careful consideration of the chemical processes is indispensable prior to designing passive acid mine drainage treatment systems. A review of the literature reveals that the majority of acid mine drainage investigations have been directed primarily toward the behavior of iron. This is due to the belief that acid mine drainage is the result of the oxidation of iron sulfides (represented in general by pyrite) in the presence of water and atmospheric oxygen. Iron is released into solution and sulfuric acid is produced in a self-propagating cycle of chemical reactions. Study of the behavior of the solution as a complete entity, including other metals commonly present in acid mine drainage has been neglected.

Stoichiometrically, the reactions are summarized by Stumm and Morgan (2) as:

(1) Initiator Reaction: $FeS_2\ (s) + 7/2\ O_2 + H_2O = Fe^{2+} + 2SO_4^{\ 2-} + 2H^+$

(2) Propogation Cycle: $Fe^{2+} + 1/4\ O_2 + H^+ = Fe^{3+} + 1/2\ H_2O$

(3) " " $FeS_2\ (s) + 14Fe^{3+} + 8H_2O = 15Fe^{2+} + 2SO_4^{\ 2-} + 16H^+$

(4) Hydrolysis Reaction: $Fe^{3+} + 3H_2O = Fe(OH)_3\ (s) + H^+$

In the first reaction, sulfur is oxidized to sulfate whereby H+ is generated and Fe^{+2} is released into solution (3). This oxidation process may be accomplished either directly by atmospheric oxygen or by the simple dissociation of pyrite in solution, followed by oxidation by aqueous oxygen (2,4). Ferrous ions are then oxidized to produce ferric ions in the first step of the propagation cycle (reaction #2). In the initial stage of the propagation cycle, the natural alkalinity of the water is sufficient to prevent ferric iron from remaining in solution, and insoluble ferric oxides are produced and precipitated forming the characteristic yellow sediment known as "yellow-boy". The formation of ferric oxides, however, is accompanied by a release of hydrogen ions, which causes the pH to decrease. When the pH has dropped enough to allow ferric iron to remain in solution, the second step of the propagation cycle begins (reaction #3). Ferric iron, a powerful oxidizing agent, assumes the primary role in the oxidation of pyrite (5). Ferric iron is reduced to ferrous iron to produce more sulfate and acidity, and then is reoxidized to ferric iron (reaction #2), and so on. For each mole of pyrite oxidized, four moles of acid are produced in the overall cycle. The ferric oxides, which precipitated during the earlier stage of the cycle (reaction #2), when the pH was above the solubility range of ferric iron, may serve as a reservoir of additional ferric ions once the pH is lowered. This allows continuation of the cycle with continued exposure of the ferric ions to solid pyrite even in the absence of atmospheric oxygen. Once this cycle is established, atmospheric oxygen no longer plays a significant part in the oxidation process (2).

The powerful oxidizing action of ferric ions may also be responsible for the release of other metals such as Cd, Cu, Pb, Zn and Mn from their sulfide forms (6,2). Ferric ion, produced in the oxidation of the pyrite that is invariably present in any sulfide ore deposit, assumes the role of oxygen thereby releasing the divalent metal ion and elemental sulfur (7).

Kinetics

The rate-determining step in the series of reactions that produce acid mine drainage is the oxidation of ferrous ion (reaction #2). Singer and Stumm (2) showed that in an abiotic system the oxidation of Fe^{+2} by oxygen was a function of pH. At pH values greater than 4.5, the rate of the reaction is pH-dependent. At pH values less than 3.5, the rate of the reaction becomes independent of pH, and the rate of the reaction is slowed considerably. Singer and Stumm (2) reported a half-time of about 1,000 days at a pH of 1. This is extremely slow in comparison to the rate of oxidation of pyrite by Fe^{+3} (reaction #3). In highly acidic pH conditions the half-time of this reaction is 20 to 1,000 minutes according to Garrels and Thompson (5).

The hydrolysis of ferric ion to produce insoluble ferric hydroxide (reaction #4) is also a much faster reaction. Experimental results reported by Stumm and Morgan (2) indicated that this reaction was also pH-independent in the low pH range, and that the presence of anions (such as sulfate) tended to increase the rate of hydrolysis.

Microorganisms

In addition to the effect of pH on the reaction process, microorganisms play a significant role in the formation of acid mine drainage. As previously discussed, the oxidation of Fe^{+2} occurs extremely slowly in the acid pH range typical of acid mine waters. Were it not for the obvious presence of a catalytic agent, the formation process would essentially cease once the pH had dropped below 5.

The acidophilic iron-oxidizing bacterium Thiobacillus ferrooxidans is generally believed to be responsible for the catalytic. T. ferroxxidans derives its metabolic energy from the oxidation of Fe^{+2}, a process that, in turn, creates the acid environment in which it thrives (pH from less than 1 to pH 4.5).

The significance of T. ferrooxidans in the formation of acid mine drainage is that it allows the continuation of the propagation cycle by rapidly providing a steady source of Fe^{+3}, the primary oxidant of pyrite. In addition, the extreme acid environment it creates allows Fe^{+3} to remain in solution thereby facilitating the weathering process.

III. Passive Treatment Mechanisms

pH Modulation

Metals can be removed from solution by increasing the pH to beyond the solubility range, the point at which the ions will precipitate as insoluble compounds (figure 1). The composition of these compounds will depend on the nature of the ions present. In general, metal ion solubility increases by several orders of magnitude with each unit decrease in pH under ideal conditions of complete dissociation of the oxide or hydroxide (8). Studies of iron solubility reported from investigations of acid mine drainage treatment systems have shown that ferrous iron will remain in solution up to pH values greater than 9.0, while ferric iron will precipitate as ferric hydroxide at pH values less than 5.0 (9,10).

pH also plays a role in the oxidation of ferrous iron. At low pH values (less than 3.5), the oxidation process is pH-independent, and is extremely slow (6). As the pH increases above 4.5, the reaction becomes pH-dependent and the rate increases (6,4). At pH values greater than 8.0, the rate of the reaction increases a hundredfold for each unit increase in pH (9,11). However, according to Gordon and Bonner (12) organic and inorganic ligands can affect the oxidation rate of iron in natural waters. Therefore the rate should be determined on a case-by-case basis.

FIGURE 1

Figure 1 Solubility of oxides and hydroxides. Free metal ion concentration in equilibrium with solid oxides or hydroxides. The occurrence of hydroxo metal complexes must be considered for evaluation of complete solubility (Stumm and Morgan 1970)

Manganese oxidation rates are also pH-dependent, and increase as the pH increases (13,14). Manganese will remain in solution for longer distances in the effluent than will iron due to the greater solubility of the divalent Mn cation, which is the predominant form of the ion at low pH values (15). In aerated waters, pH values of 10 or higher may be necessary to precipitate the oxide (10). The actual rate of oxidation in natural environments has been observed to be higher than that predicted, and it is believed that the process is also influenced by microorganisms (12).

Aeration: Aeration is one method of pH modulation available in a passive treatment system. As mineral acidity (H+) is neutralized, carbonic acid is produced from the evolved carbon dioxide. This tends to buffer the pH and low pH values may be maintained. Under tranquil flow conditions, a maximum pH of 6 to 6.5 is predicted, which is the point at which calcium carbonate reaches a saturation equilibrium (10,20). The buffering effect and approach toward solubility limits tends to slow the neutralization process in the pH range of 4 to 8 (20). The pH may be increased, however, by adding turbulence to the water. Aerating the water allows the carbon dioxide to be liberated (exsoluted) to the atmosphere thereby reducing the concentration of carbonic acid (16). Gordon et al. (15) reported a pH value of 8.4 as being associated with carbon dioxide stripping.

The result of pH increase as a function of carbon dioxide removal is presented in figures 2,3,4, and 5.

FIGURE 2

Figure 2 Observed pH - Load Factor Relationships. The upper and lower curves are computed values for the limiting CO_2 cases, i.e.

1. All of the CO_2 generated is driven off.
2. None of the CO_2 generated by the dissolution of limestone is lost.

The observed values fall between these two extreme cases. (Duncan 1982)

FIGURE 4

FIGURE 3

Figure 3 Process design curves for tranquil flow through barrier and before exsolution of carbon dioxide

FIGURE 5

Figure 5 Process design curves for violently turbulent flow through the barrier such that carbon dioxide is released instantaeously (Pearson and McDonnell 1975b)

Limestone Neutralization: Limestone is frequently used in conventional mine drainage treatment systems for pH modulation, to enhance iron oxidation and to neutralize acidity. In the neutralization reaction, sulfuric acid combines with dissolved calcium carbonate to produce calcium sulfate, water, and carbon dioxide:

$$(5)\ H_2SO_4 + CaCO_3 = CaSO_4 + H_2O + CO_2$$

Ferric ions, produced during the oxidation of ferrous iron, react with calcium carbonate to form insoluble hydroxides (reaction #6):

$$(6)\ Fe_2\ (SO_4)_3 + 3CaCO_3 + 3H_2O = 2Fe(OH)_3 + 3CaSO_4 + 3CO_2$$

The neutralization of acidity by limestone is controlled by the following reactions according to Pearson et al. (17,18,19).

$$(7)\ CaCO_3\ ^{(s)} + H^+ = Ca^{++} + HCO_3\ ^-$$

$$(8)\ HCO_3\ ^- + H^+ = H_2CO_3$$

$$(9)\ H_2CO_3 = H_2O + CO_2(g)$$

Because equations 7 and 9 are heterogeneous, they are the slowest of the three reactions and are therefore rate-limiting. According to Duncan (19), the effects of temperature, ionic strength, and intensity of turbulence can be neglected and the rates of equations 7 and 9 are dependent only on the concentration of mineral acidity (H+) and the concentration of dissolved carbon dioxide.

Additional factors that must be considered in limestone neutralization treatment are particle size and limestone composition. As particle size increases, the quantity of limestone required also increases. In general, the smaller the particle, the greater the surface area per unit volume. Increased surface area enhances the reactivity (21). Increases in the magnesium content of the limestone will also increase the quantity of limestone required. Neutralization efficiency increases as the Ca/Mg ratio increases, thus calcite is more suitable than dolomite or magnesite (10). Limestones composed primarily of pure calcium carbonate have been shown to be the most efficient neutralizing agents (11). Equally efficient are low calcium limestones containing calcite and a large surface area.

Limestone coating or armoring may occur even at low concentrations of metal ions. Armoring will result primarily from the deposition of aluminum oxides and clays. This effect may reduce the reactivity of the limestone to 20 percent of that of clean limestone, but will not completely deactivate the neutralization process (Kleinmann, 1983, 1984; Duncan, 1982).

Temperature does not have a great influence upon the neutralization reactions. While reaction rates and the behavior of dissolved ions are influenced by changes in temperature and pressure, the effects of moderate departures (a few atmospheres, or plus or minus 10 to 15 deg C.) from standard conditions (1 atmosphere, 25 deg C.) are not significant (Hem, 1970; Duncan, 1982).

Cation Exchange

The primary mechanism for the removal of dissolved metals in a passive treatment system is through cation exchange. Both sphagnum moss and peat have high cation exchange capacities. Certain zeolites may be used for this purpose, as well. However zeolites are more costly, not as readily available, and require more frequent maintenance than peat and sphagnum.

Sphagnum: Cation exchange in sphagnum is believed to take place within the submicroscopic channels in the cellulose of cell walls. The cell walls become impregnated with pectic and phenolic compounds, and a zeolite-like structure results. Sphagnum recurvum and sphagnum fibriatum have been shown to be extremely effective in removing Fe^{+2} from acid mine drainage water. In studies by Kleinmann, ferrous iron concentrations were reduced by 88% on the average and total iron removal averaged 50 to 60 percent(24,39). Nearly all of the iron removal was accomplished within the first 12 linear feet (approximate volume, 12 cu ft) of the sphagnum mat. The sphagnum was

ineffective in removing sulfate, Mn, Ca, Mg, and Al, however. Concentrations of these ions remained virtually unchanged after passage through the moss. Concentration of other ions such as Zn, Pb, Cu, and Cd were not mentioned. Acidity and pH were not significantly altered by the sphagnum. The cation exchange capacity of the moss was periodically monitored and found to remain high throughout both studies (24,39).

Although in Kleinman's study, the sphagnum was under stress at times due to inundation and the lack of an organic substrate, it remained viable(24). This may account for the consistency of the high cation exchange capacity values. New exchange sites are undoubtedly produced as the moss grows. Viability should be improved when the moss is grown under natural conditions, which should in turn improve the maintenance of high cation exchange capacities. The relationship between the rate of saturation and growth rate is still unknown, however. The effects of iron hydroxide clogging are also unknown. The following conclusions have been drawn from several investigations of the cation exchange properties by sphagnum by Bell, Clyma , and Kleinmann (22,23,24):

1. Trivalent and divalent ions are more readily adsorbed than monovalent ions in solutions containing Fe, Mg, and Ca in concentrations similar to those of natural waters.

2. Cation exchange sites persist either through metabolic regeneration or through creation of new sites in the hydrogen form.

3. Anion exchange abilities of sphagnum are negligible compared to cation exchange abilities.

4. Cation exchange capacity decreases with increasing pH and/or increasing cation concentration.

Peat: Peat is an organic material that results from the partial decay of plant material. When vegetative matter falls into water or onto soils that are continually saturated with water and where atmospheric oxygen is largely excluded, bacterial decomposition is greatly inhibited and the partially decayed matter accumulates.

The cation exchange properties of peat are attributed to the humic acids found in peat. Humic acids are derived from the partial decay of plant tissues. The precise mechanism of humus formation and the chemical definition of humic acid are not known (25). The structure of humic acid molecules is not well understood either. Humic acids have a high, widely-varying molecular weight. Krauskopf (26) and Forstner (27) defined various types of humic acids according to the molecular mass. Humins have the highest molecular weight, followed by humic acids and fulvic acids, which are the lightest of the three groups and are the most soluble form of humic substance. Fulvic acids appear to have a higher exchange capacity than humic acids (28). Forstner attributes this to the large number of functional groups present in the low-molecular mass of fulvic acid and to the greater solubility of the acid.

The total cation exchange capacity of peat has been reported by a number of investigators. Given and Dickenson (28) summarized a number of these investigations, and reported a range of 20 to 200 meq/100 gm dry peat. Fuchsman (29) reported hydrogen exchange capacities per 100 gm of humic acid at pH values of 4.5, 6.4 and 8.1. They were 170.0, 286.3 and 400.0 meq/100 gm, respectively. Forstner et al. (27) reported similar values. These examples of total cation exchange capacities for peat gave no indication of the conditions under which the capacities were determined.

Forstner (27) and Moore et al. (30) stated that the bonding ability of humic acids was 3 to 4 times greater for divalent metal ions than for trivalent ions. Jonasson, as reported by Forstner(27), gave the following order of bonding strength for various divalent metal ions on humic or fulvic acid:

$$UO2 > Hg > Cu > Pb > Zn > Ni > Co$$

The cation exchange ability for peat appears to correlate with the pH of the environment, generally decreasing with increasing pH, as in the case of sphagnum. Peat is known to possess high water retention capabilities and moss peat may hold as much as 15 to 30 times its own weight in water (31). Once the peat is dried, however, much of the water retention capability is lost, and the peat becomes essentially impermeable to water.

The use of raw peat as a cation exchanger in acid mine drainage waters may pose some problems. As previously stated, raw and dried peat is virtually impervious to water. Establishing flow through the peat may be difficult. If the peat remains impermeable, water will simply flow over the top of the bog thereby reducing contact area and time and lowering the exchange rate. Fulvic acid is readily leached from raw peat over a broad pH range. The acid is extremely soluble and complexes easily with metal ions. As a result, metals may remain in the effluent for longer distances. Humic acid, which begins to dissolve at pH 6, may also be leached. Therefore, although peat may possess good exchange capacities, its physical characteristics may limit its usefulness in a passive treatment system.

Sulfuric acid treated peat may offer several advantages over the use of natural undried, untreated peat. The sulfuric acid treatment involves heating dried peat in the presence of concentrated sulfuric acid (4.0 ml to 1.2 grams dried peat) at 150°C for 2 hours. Acid treatment greatly improves the flow-through characteristics and thus will allow greater contact between the water and the exchange sites. Fulvic acid leaching does not begin until pH levels are raised to above 7 or 8 if the peat is acid treated. Treating peat in this manner tends to equilibrate the cation exchange capacities of peats from different locations as well. Flow rate, pH, and the presence of competing ions are the primary factors that determine the effectiveness of heavy metal ion removal by sulfuric acid treated peat. These factors can in part be compensated for by providing a sufficient excess of exchange sites. Ansted (40) found that by increasing the ratio of meq of exchanger to meq of metal ions from 6.25 to 20.8, the simultaneous recovery of a mixture of metal ions was essentially 100%.

Sulfuric acid treated peat also offers an advantage over the use of sphagnum moss in that sulfuric acid treated peat has been shown to be highly effective in the removal of Mn, whereas sphagnum appears incapable of reducing Mn concentrations. Sulfuric acid treated peat has also been shown to be highly effective in the removal of Zn^{+2}, Pb^{+2}, Cd^{+2}, and Cu^{+2}, whereas the removal of these ions by sphagnum has not yet been observed.

The two primary disadvantages to using sulfuric acid treated peat in a passive treatment system are the difficulties associated with the acid treatment process in the field, and the fact that sulfuric acid treated peat is not self-regenerating. Large scale production of sulfuric acid treated peat has not yet been attempted and the logistics of such production will have to be assessed. Once the peat becomes saturated with metal ions, it will have to be replaced and either regenerated or discarded. Both of these factors will increase the level of maintenance of the treatment system.

Sorption and Coprecipitation

Sorption of heavy metals such as Co, Ni, Cu, and Zn by hydrous Fe and Mn oxides may be a principle controlling factor in the distribution of these metals in solution (32). Sorption (and desorption) of these metals is dependent upon a number of factors, but is primarily controlled by pH. pH values must first be high enough to allow the formation of Fe and Mn oxides. In the low pH range of acid mine drainage, manganese oxides may never be

present. Ferric hydroxide may be present, but it is incapable of sorbing positively charged metal ions at pH values below 5.2. In addition to pH controls, if sufficient metals extraction is provided by the ion exchange medium in the treatment system, neither of these oxides may be present in sufficient quantities to provide significant sorption effects. Thus, the effects of sorption and coprecipitation may not be significant mechanisms for passive mine drainage treatment.

Complexing

The phenonemen of metal ion complexing is often cited as the reason for the presence of metals in solution at Eh/pH values outside the range of stability of the soluble form of the ion. Complexing is also believed to inhibit the oxidation rates of soluble Fe^{+2} and Mn^{+2}, thereby inhibiting the rate of precipitation of the less soluble oxides, and decreasing ion exchange and adsorptive capabilities (2,27). Gordon (15) and Gordon and Bonner (12) cited the inhibitory effects of tannic acid, glutamine, and humic ligands on the oxidation of Fe^{+2} in natural waters. They also referred to the enhancement of Mn solubility in the presence of tannin, carbonic acid, and lignin.

Complexing of metal ions with humic and fulvic acids may reduce cation exchange capabilities. Rashid, as reported by Forstner and Wittman (27), stated that one-third of the total bonding capacity in humic matter may be attributed to cation exchange, while the remaining two-thirds are attributed to chemical sorption and organic complexes. Hem and Durum (33) reported the following sequence of divalent metal ion-fulvic acid complex strengths at pH 5:

$$Cu > Pb > Fe > Ni > Co > Zn$$

Biological Extraction

Metals extraction may be provided by microorganisms and by plants growing in or near the effluent. Bacteria, algae, and fungi will affect dissolved metal ion concentrations either by direct accumulation of the metals within their body structures or by producing sufficient changes in the aqueous environment to facilitate precipitation of the metals from solution.

The iron bacteria Gallionella, for example, is known to accumulate dissolved iron from solution, which in turn is secreted by the organism in long strands of hydrated Fe^{+3} oxides. The bacterial cell lives at one end of the group of strands. The secreted oxides form a spongy, rust-like crust on the effluent substrate. Gallionella may also accumulate manganese in a similar manner (34,15). Sulfate reducing bacteria, Desulfovibrio and Clostridium, indirectly remove metals from solution by generating hydrogen sulfide under anaerobic conditions. In the presence of hydrogen sulfide, metal ions form insoluble sulfides and precipitate (10,35).

Oborn (36,37) and Oborn and Hem (38) have examined the effects of aquatic biota on iron in natural waters, both experimentally and from the literature. Iron is removed from water most vigorously during the active growing season and returned to the water upon death and decay of the organism. Bacteria may deposit iron released in this fashion as iron ores at the water-sediment interface where dissolved oxygen is depleted.

Martin (8) suggests the use of Eichhornia Crassipes (water hyacinth) as a means of treating acid mine drainage. Water hyacinths are effective in the removal of lead, mercury, and other metals, and are capable of concentrating the metals as much as 10,000 times that of the ambient solution concentration. Water hyacinth has been suggested as a possible aquatic species to be used in the bog. Since water hyacinth is a tropical/subtropical plant, it is unlikely to survive the winters at high elevations. Duckweed is often used in combination with water hyacinth, since it is more resistant to freezing temperatures (41). Duckweed, however, forms a thick mat over the water surface that tends to deplete the dissolved oxygen content and Eh of the water. Water hyacinth forms a similar type of mat, but does not reduce the dissolved oxygen or the Eh (38). Toxicity of the effluent on the plants and the effects of bioaccumulation and biomagnification on plant consumers must also be considered.

Kleinmann (39) suggested that anoxic conditions in the bog may be desirable. The production of hydrogen sulfide gas would utilize the excess hydrogen ions produced in the cation exchange reactions in the bog and metal ions, precipitated as insoluble sulfides, would be more permanently immobilized than in the plant tissues of the bog. The effectiveness of other acidophilic plant species native to the Southern Rocky Mountain region is unknown.

Dilution

Dilution provides the principal treatment for most streams impacted by mine drainage which have not been treated by other interventions. The dilution effect of tributary streams may be attributed to the natural bicarbonate buffering systems of the incoming waters. The buffering effect may be destroyed, however, if the acidity of the receiving stream is too high or if calcareous materials are not readily available in the tributary streams. Dilution may be important in neutralizing acidity unaffected by the limestone, but its importance will depend on the performance of the limestone beds.

IV. Passive Treatment System Design

The process of designing a passive treatment system is dictated by both chemical and physical constraints. Theoretical assessments of the primary chemical processes involved in passive treatment of acid mine drainage are vital to the design process because they determine the type and quantities of materials (peat, limestone, etc.) necessary to achieve desirable treatment goals, they determine the most efficient arrangement of the system components, and they facilitate predictions of expected results. The results of the theoretical assessments then must be adapted to the physical and engineering constraints of the site. The treatment system must be designed to function for long periods of time through extremes in weather conditions, flow conditions and variations in water quality at the site with minimal

maintenance required while continuing to provide adequate treatment. In most cases, installation of passive treatment systems cannot involve major alterations of the existing landscape in the vicinity of the mine discharge. The process of designing a system that will achieve optimum results therefore requires addressing that which is theoretically possible within the physical constraints of a particular site.

General Site Evaluation

A general evaluation of the watershed affected by the mine drainage is required to delineate the physical, engineering and legal constraints of the site, and to define the nature and extent of the problem. Information which is especially important includes detailed descriptions of the local topography and mine configuration, the method of mining, and the local geology. Water rights information, local land use policies and current landownership patterns must be known. Soil types in the area must be defined in order to determine runoff volumes. Vegetation types must be determined to facilitate reclamation of the site following installation of the treatment system. Local climatological data, historical water quality data and flow data must also be provided. Much of the information necessary for site evaluation is available from the literature and other accessible information sources (e.g. large scale topographic maps, mine maps, soils, and vegetation surveys, etc.) prior to any site visitation.

Hydrologic Investigations

Detailed hydrologic information is vital in the design of a passive treatment system. Any structure incorporated into the design should be capable of passing a 100 year storm event. Therefore, the watershed contributing to the flow of the mine discharge must be carefully evaluated from the standpoint of peak flow runoff.

Next, the flow regime of the mine discharge and any springs and minor tributaries which contribute to it's flow must be evaluated. Historic records of flow measurements can be extremely helpful. Seasonal variations in the mine discharge and hydrologic responses to such activities as irrigation practices, nearby mining activities, water storage facilities etc., should be assessed.

Fairly detailed stream channel measurements of the mine drainage are necessary. Both longitudinal and cross sectional profiles must be prepared from actual surveys. Such information is essential for the evaluation of alternate locations for the components of the treatment system.

A baseline water quality monitoring program which is integrated with the flow measuring system must be established as early as possible in the design process. A minimum of a year's worth of pollution loading data (pollutant concentration x flow) should be available for the mine discharge prior to the design and construction of a passive treatment system. The number of water

quality samples taken, the number of sampling sites and the range of parameters analyzed must be determined on a case by case basis. Factors to be considered in this determination include the flow regime of the mine drainage, the geochemical properties of the ore body or coal seam which was mined, and the soils in the watershed area. Additional water quality considerations include the range of beneficial uses in effect for the mine drainage and it's receiving streams and any applicable water treatment and discharge regulations.

Selection of Treatment Materials and Components

The selection of treatment materials should be based on theoretical considerations and the results of previous treatment projects. At the present time limestone appears to be the most suitable material for neutralizing acidity in a passive treatment system. Selection of the limestone should be based on Ca/Mg ratios since these ratios will in large part determine the quantity of stone that will be required. The selection of a cation exchange medium is less definitive at this time. Sphagnum moss and peat, either raw or acid-treated offer the best possibilities for metals extraction, although the advantages and disadvantages of each must be carefully weighed prior to the final selection. Aeration can be provided by riprap, groins and gabions, cascades and waterfalls. The selection of treatment materials and the design of the individual components are made following the site evaluation and hydrology investigation.

Determination of Structure Locations

Siting of treatment structures is accomplished with the aide of the channel profile and cross section surveys conducted during the hydrologic investigation. Generally, cation exchange systems for metal removal will be located upstream of neutralization and aeration structures. This will help to minimize coating and clogging problems on the neutralization medium. Also, acidity is released in the cation exchange process.

The placement of any structure in the channel where the channel does not follow the natural gradient may call for channelization or realignment of the stream course at those particular points to avoid "short-circuiting" around the structures after installation.

Construction and Reclamation Plan

The elements of a passive treatment system construction plan include equipment and material specifications, excavation diagrams, structure installation instructions, and site reclamation procedures. The plans must be detailed enough so that contractors unfamiliar with passive treatment pricipals can construct the system and rehabilitate the disturbed area with minimal supervision.

System Evaluation and Monitoring Plan

Given the relative novelty of passive treatment techniques and the lack of data concerning their performance and efficiency, every installation should be evaluated and monitored. The monitoring plan should address water quality and treatment efficiency in terms of acidity and metals removal, as well as performance of individual components. Data derived from these evaluations will aid in the development of design criteria for future passive treatment systems.

V. Design Example: Marshall No. 5 Passive Mine Drainage Treatment System

The Marshall No. 5 coal mine is located one-half mile south of the town of Marshall and 4 miles south of Boulder, Colorado. It is one of the few inactive coal mines in Colorado which discharges a significant amount of metaliferrous, acidic water. While the water emanating from the mine is not particularly toxic, the drainage offers an excellent demonstration site for a passive mine drainage treatment system.

General Site Evaluation

Mine Configuration: This mine was operated by the Marshall Coal Company intermittently from 1863 to 1939. This company operated a complex of seven mines in the area of the No. 5 Mine. The mine was a drift room and pillar type operation encompassing about 2 acres of underground workings..

Geology and Mining: The Marshall Project area is located in the Denver Coal Region and the Boulder-Weld coal field. Geologically, the project area is underlain by the Larimie formation(s) which dep 4 degrees to the east-southeast. The coal seams in the area lie within a sequence of sedimentary rocks consisting of interbedded shales, claystones, sandy shales, coal beds, and then beds of sandstones. The coal seam mined at the Marshall No. 5 Mine was ranked subituminous and was 8.0 - 9.0 feet thick. There is no further coal analysis information available.

Baseline Soils and Vegetation: Three types of soils are present at the study site: Te (terrace escarpments - hydrologic soil group B), Ro (rock outcrop - hydrologic soil group D), and HaD (Hargraeve fine sandy loam - hydrologic soil group B) (43,44). It was assumed for this study that 90% of the study site (watershed area) is covered by soil types Te and HaD, with the remaining 10% covered by soil type Ro. Soils are shallow and in many areas are merely a thin layer of cobbles over sandstone or shale.

Vegetation at the site is composed primarily of mixed grasses and herbaceous materials. Brush, shrubs, and some ponderosa pine are present in areas and pockets where soil moisture is retained. Several small areas are present where surface disturbances from mining have weakened or destroyed the mature native plant communities. These areas have been invaded by pioneer and transition plant species.

Local Climatology: Average annual precipitation in the project area is 18.5 inches. Regionally the area is characterized by a high plains, continental climate regime. Prevailing winds are from the west. The average growing season is approximately 148 days.

Land Use: In the past, the primary land use was for grazing and mining. At present, the major land uses are grazing, recreation, and residential.

Landownership: The area surrounding the Marshall No. 5 coal mine is Boulder city open space. Consent for reclamation work has been obtained from the Boulder Open Space Board.

Hydrologic Investigations

Surface and Ground Water Regime: The perennial flow from the Marshall No. 5 Mine is the sole expression of ground water on the site. The mine discharges 17 to 70 gallons of water per minute. Repetitive flow measurements of the mine discharge has shown very consistent results. Surface water from the project area is drained by Marshall Creek which flows into South Boulder Creek. Both of these streams are perennial drainages. The drainage basin or watershed in the immediate vicinity of the Marshall No. 5 coal mine adit encompasses approximately 14 acres.

Water Quality: Observed iron concentrations range from 3,500 - 7,200 mg/l and manganese levels average 1,400 mg/l. Zinc concentrations average 98 mg/l and lead levels remain constant at 17 mg/l. pH values range from 4.2 - 4.5. The drainage contains little alkalinity (8 mg/l), but sulfate concentrations are elevated to 340 mg/l. Repetitive water quality sampling of the drainage has shown very consistent results.

Peak Runoff from 100-year, 24-hour Storm: The peak flow or the study watershed was found to be 3.89 cubic feet per second (cfs) using the methodology developed by the Soil Conservation Service of the U.S. Department of Agriculture (42,43,44). Structures to be installed in or near the drainage channel must therefore be designed to safely pass and/or withstand 3.89 cfs.

Stream Channel Measurements: A total of 10 cross-sections were measured at 50 foot intervals beginning at the mine adit and continuing downstream for 450 feet. The longitudinal stream profile (Figure 6) was surveyed over the same distance. Large trees and thick underbrush prohibited further surveying downstream from that point. It was felt, however, that the major inflection points in the stream had been determined within this distance, and that all of the passive treatment structures would be placed along this upper reach of stream.

Baseline Water Quality Monitoring Program: The U.S. Geological Survey has sampled and analyzed the water draining from the Marshall No. 5 coal mine over the past 7 years. This data is available through the STORET automated water quality information system. In addition the Colorado Inactive Mine Reclamation Program has sampled this mine drainage over a 3 year period.

FIGURE 6

LONGITUDINAL PROFILE
DRAINAGE FROM MARSHALL NO. 5 COAL MINE

Kaman Tempo

There is a suprising degree of consistency in the concentrations of water quality parameters sampled in these investigations.

Water Quality Regulations: The requirement for a point source discharge permit was waived by the Water Quality Control Division of the Colorado Department of Health due to the novelty of the project. The "404" Dredge and Fill Permit was also waived due to the minute quantities of flow from the mine.

Water Rights: There is a legal water right for the water issuing from the Marshall No. 5 Mine. The presence of the right necessitated a written consent from the owner for right of entry to construct the Marshall No. 5 passive treatment system. The owner of the water rights maintains the right to inspect monitoring devices (weirs) above and below the system to insure that the treatment system does not decrease the quantity of water.

Selection of Treatment Materials and Components

The Marshall No. 5 treatment system is composed of three components. The first is a small rock check dam composed of durable limestone or river rock behind which is placed a heavy layer of natural peat moss. Sphagnum moss will be transplanted onto the surface of the peat "bog". The peat moss will provide heavy metals extraction through cation exchange. The second component of the system is a series of small drop structures placed in the channel to provide aeration. Limestone cobbles compose the third component. These cobbles will be placed below the drop structures to armour the stream channel and to provide a source of alkalinity for the neutralization of mineral acidity.

The proposed configuration and selection of materials for the Marshall #5 treatment system is in accord with the information derived from the literature with the exception of the use of natural, untreated peat for cation exchange. One of the outcomes of the field demonstration will be an evaluation of the permeability characteristics of natural peat in this application. If permeability problems are encountered which cannot be overcome with minor modifications to the bog, the natural peat will be replaced with acid treated peat. At this time the determination of the quantities of materials necessary for optimum treatment efficiency is largely dictated by spatial constraints and materials availability.

Determination of Structure Locations:

Based on the stream channel profile (and resultant gradient) and the cross-sections, it appears that the most suitable locations for the check dam peat bogs are within the first 150 feet downstream from the mine adit or downstream of the "falls" (which are approximately 330 to 340 feet downstream of the adit). In these areas the stream course appears to be following the natural gradient, whereas from 150 feet to 300 feet downstream from the adit, the stream seems to follow an old mine road or path instead of the topographic lows (natural gradient).

At a distance of approximately 300 feet downstream from the adit, where the "falls" occur (see Figure 6), a vertical structure containing limestone is feasible. This structure allows for the neutralization of acid drainage, while allowing the flow to pass through at a relatively fast rate, thereby prolonging the life of the limestone.

There are several feasible locations for drop structures. The relatively low gradient probably precludes the use of riprap to cause turbulent flows without first increasing the gradient. The natural flows are generally too small and too slow to provide a noticeable increase in aeration by using riprap. However, by using drop structures to increase the gradient in various locations, aeration may be increased. It appears that the most feasible locations for the drop structures are between 50 and 300 feet downstream from the adit.

Construction and Reclamation Plan

The following equipment is necessary in order to install the treatment system: tractor/loader/backhow, sheepsfoot compactor or vibratory compactor, dump truck, flat bed truck, water truck, water pump, 4" flexible hole (75'), revegetation equipment.

Materials necessary for the work include: 20 cu yds natural peat moss, 1.5 cu yds pure crushed limestone (size 2" to 3" diameter), 15 cu yds river rock (size: 3" to 4" diameter), 0.5 cu yds pea gravel, 25 sq yds of Marafi 140-S filter fabric, approximately 50 wooden stakes and 60 board feet of 1 x 6" wooden boards. Three steel weirs (A-36 gauge) primed and asphalt coated and measuring 3' x 5', will serve as drop structures.

The excavation for the peat bog is a wedge shaped cut measuring 5' high by 60' in length and 10' in average width. The material to be excavated appears to be saturated. Plan view and cross section views of the peat bog are presented in Figure 7. The bottom of the excavated area shall be compacted by

FIGURE 7
PEAT BOG

making multiple passes (20-30) over the excavated area with a suitable piece of heavy equipment or sheepsfoot or vibratory compactor. The 1" x 6" wooden boards shall be placed on edge using the stakes to direct the underflow in the bog in a meandering fashion. Mine drainage shall be diverted from the weir structure around the area of excavation in a 4" flexible hose prior to construction of the simulated peat bog. This temporary diversion shall remain in-place for the duration of the bog construction work. The river rock and filter fabric shall be placed as shown on the "Peat Bog" diagram (Figure 7).

Three asphalt coated steel drop structures are to be prefabricated and installed by the contractor. The drop structures will be keyed a minimum of 1.5' into each side slope to ensure stability and to prevent flow around the edges of the structures. The area below the drop structures shall be excavated according to the dimensions shown on the attached "Design Criteria for Drop Structure". Each excavation shall be filled with loose limestone in the configuration shown on the attached "Design Criteria for Drop Structure."figure * All earth material excavated during construction of the V-Notch Weir simulated peat bog and drop structures will be stockpiled in a controlled manner which minimizes the area of disturbance. All material in excess of the amounts necessary for backfilling around installed structures will be removed from the site as specified in the site clean up provision which follows below. However, if the excess material is found to be suitable as a plant growth medium, the material can be spread on the surface of the disturbed areas as topsoil in accordance with the Disturbed Area Regrading specifications which follow below.

All excess excavated and stockpiled material, excess gravel, river rock, limestone, peat, boards, wooden stakes and any other garbage and debris remaining on-site as a result of construction activities should be promptly removed from the site and disposed of at the nearest city or county approved land fill. This material may be salvaged by the contractor. All areas disturbed during construction are to be regraded to a smooth land form which provides proper drainage through the area and which blends in with adjacent undisturbed area topography. Following regrading, all disturbed areas including access ways are to be ripped or chiseled to a depth of 4"-6" (rip cuts on maximum 12" centers) in order to alleviate compaction and provide a suitable seedbed.

All ripped or chiseled areas shall be fertilized and revegetated using species which are well adapted to the site. All areas broadcast seeded shall be tilled with a disk harrow or other suitable device in order to cover the seed prior to mulching. This operation is not required on areas drill seeded. Straw mulch (pest or weed-free to the extent possible, not moldy or rotten) will be surface blown or otherwise evenly spread onto all seeded areas.

System Evaluation and Monitoring Plan

The performance of the Marshall No. 5 passive mine drainage treatment system will be evaluated carefully. Because of the inclusion of weirs in the design of the drop structures it will be possible to accurately measure the impact of the system upon the volume of mine water passing through it. Also, accurate flow measurements are essential to assess treatment efficiency in terms of acidity and heavy metals removal. Water samples will be collected from

stilling basins behind the three weirs, and at a point further downstream. In addition, peat and limestone samples will be analyzed to determine cation exchange rates and to evaluate limestone coating. The monitoring program will be conducted over a 12 month period with sampling frequency decreasing as the variance in parameter concentrations is determined.

Many other system performance characteristics will be evaluated including; natural peat permeability, sphagnum (S. recurvum V. brevifolium) transplanatability onto natural peat saturated with acid mine drainage, and the efficacy of acid treated peat in this application.

VI. Treatment System Cost

The cost of the Marshall No. 5 passive mine drainage treatment system is considered in three phases: feasibility and design, construction, and system evaluation.

Treatment Feasibility and Design Costs	
General Site Evaluation	$1,500.00
Hydrologic Evaluation	$1,290.00
System Design	$2,290.00
total	$5,030.00

Treatment System Construction Costs	
Materials	$ 750.00
Equipment Rental	$2,800.00
Labor	$2,300.00
total	$5,850.00

System Evaluation	
Water Sampling and Analysis	$3,600.00
Peat and Limestone Analysis	$ 600.00
total	$4,200.00

VII. Conclusions and Recommendations

Acid mine discharges from inactive mines are perpetual point sources of pollution which can wreak havoc upon receiving streams. Access to inactive mine drainage problem areas is often severely limited. Therefore, pollution control measures which do not require constant electrical or chemical inputs and frequent operation and maintenance activities are most desirable. "Passive" mine drainage treatment approaches are designed to control pollution from mine effluent using techniques which emulate and enhance naturally occurring metal and acidity removal processes. Natural geochemical processes such as pH modulation and neutralization, aeration , dilution, cation exchange and adsorption, sorption and co-precipitation are relied upon to achieve these objectives, at the effluent source.

Basic components of a passive treatment system include an ion exchange medium, a neutralization medium, and an aeration device. An organic ion exchange medium, such as a peat bog with sphagnum moss, seems to offer the best potential for metals extraction in a passive treatment system. Limestone, high in $CaCO_3$, appears to be the most suitable material for neutralizing acidity. Limestone is used for flow barriers or riprap in cascades and for energy dissipation and channel armoring, below waterfalls. Waterfalls, cascades or gabions provide aeration and carbon dioxide exsolution, increasing the dissolved oxygen in the effluent and helping to raise pH.

The process of designing a passive treatment system is dictated by both chemical and physical constraints. Assessments of the primary chemical

processes involved in a given acid mine drainage determine the type and quantities of materials (peat, limestone, etc.) necessary to achieve desirable treatment goals. They also determine the most efficient arrangement of the system components. Generally, cation exchange systems for metal removal will be located upstream of neutralization and aeration structures because acidity is released in the cation exchange process. This configuration also helps to minimize coating and clogging problems on the neutralization medium. The selection of treatment materials and the design of individual components for passive treatment systems are made following detailed site evaluations and hydrologic investigations. The Marshall # 5 Passive Mine Drainage Treatment System Design is presented as an example of this design process.

Every passive treatment installation should be evaluated and monitored. The monitoring plan should address water quality and treatment efficiency in terms of acidity and metals removal, as well as performance of individual components. Data derived from these evaluations will aid in the development of passive treatment design criteria for future systems.

PASSIVE SYSTEMS FOR AMD TREATMENT

Several passive systems have been observed in nature as described by HOLM, BISHOP, and TEMPO (?) whose paper is inserted here.

HOLM and GUERTIN (1984) describe the design of a passive system for AMD abatement employing a cascaded flow of AMD over limestone rocks in such a way as to provide a high degree of attrition and aeration. This was followed at the abandoned Marshall Mine near Boulder, Colorado, by a settling area and polishing by aquatic plants in an ecologically engineered bog. Their paper is inserted below.

PASSIVE SYSTEM #1: MARSHALL NO. 5 COAL MINE, BOULDER, COLORADO

The idea of maintaining and funding a water treatment facility in perpetuity to treat AMD is not at all attractive. The cummulative cost to a company, and even to the national economy, of treating acid mine drainage from the same site over a period of say 200-400 years would be high. If a mine or waste impoundment cannot be restored to achieve a satisfactory walk-away situation, the next best thing is to employ a passive water treatment system which, hopefully, will work for years without attention. More information on the later results of the field tested passive AMD treatment facility are most encouraging, and further details can be requested from J. David Holm whose address is given above.

PASSIVE SYSTEM #2

The U.S. Bureau of Mines at the Bruceton Research Station just south of Pittsburgh has experimented with a passive AMD treatment system using plants, particularly sphagnum moss. Their work has developed to the point of building a pilot scale mobile perspex portable bog which was transported from site to site on an experimental and demonstration basis. Further field evaluations and tests are in progress with interesting results and observations.

A sphagnum moss bog was shown to be capable of oxidizing ferrous to ferric ions which then are partly precipitated and removed in the bog. It was anticipated that a final polishing of effluent would be achieved by limestone neutralization also in a passive system since earlier work by the USBM and others indicated that limestone more effectively removes ferric than ferrous ions.

Phase I of a test demonstration program with the Portabog system was completed for the USBM and reported on in May, 1983, by PEER CONSULTANTS and BREHM LABORATORY (1983). The results were not as encouraging as had been hoped because

of difficulties in stabilizing the portable bog. In actual bog conditions alongside coal mine spoil banks, AMD flowing in with very high ferrous ion levels and low pH were found within 10 feet of the inflow point to have been almost completely oxidized to ferric and that pH increased from around 2 to 4. Ferric hydroxide also tended to be coagulated and flocculated by the plants and, on settling to the anaerobic zone of the bog some way below the surface, there was evidence of conversion from ferric hydroxide to ferrous sulfide by reaction with H_2S generated in situ by anaerobic microbiological activity which gets its energy from decaying plant biomass below the surface and sulfates in the water.

Further work on this system will undoubtably be carried out in due course. Meanwhile, additional information might be available from:

PASSIVE SYSTEM #3 - AMAX LEAD COMPANY, BUICK MILL

The following accounts were extracted from tests that are 10 years old and may well be out of date. Two major effluent streams produced from the mine and mill at AMAX's Buick Mill, which recovers zinc and lead concentrates, are 1,000 gpm (5,680 m^3/d) underground mine water pumped directly to the primary tailings pond and mill tailings wastewater released at 15,000 m^3/d to the same tailings pond.

In the 425 acre-feet (523,000 m^3) tailings pond, heavy particulates settle out, and decanted water discharges at a rate of 3785 m^3/d through a spillway to a stilling pond and then to a series of shallow meanders. In these meanders, algae are encouraged to grow providing a trap for fine particles and heavy metals. Finally, a 100 acre-foot (123,350 m^3) sedimentation pond followed by a baffled outlet prevented the algae from discharging into the receiving stream, Strother Creek. The system had a calculated retention time of 60 days. The effectiveness of the system has been documented by JENNETT and HARDIE (1974), and an investigation into its effectiveness in removing trace organics was made by JENNETT amd WIXSON (1977). The system was developed in conjunction with a research team from the University of Missouri - Rolla. It appears that some constituent in flotation mill tailings encourages the growth of algae, and there has

been some speculation that it may be residual flotation reagents or their degradation products.

The combined mine-mill effluent of the Buick Mine constitutes the major volume of the stream waters of the receiving stream. Due to the location of the tailings lagoons some two miles from the mill with about a 100-foot drop in elevation, it was difficult if not impossible to recycle millwater or to separate the mine water.

The meander modification of this treatment plant was developed when laboratory and field data indicated that algae effectively removed heavy metals and trace nutrients.

Algae detach themselves periodically during their life cycle so it was necessary to construct a final polishing lagoon at the end of the polishing system. This small lagoon provides further retention time for the effluent in order to settle accumulated and dislodged algae and aquatic plants and their accompanying heavy metal solids. A detailed study was completed by ERNST (1976).

Figure 30A indicates the levels of lead found in the algae below Strother Creek operations before the meander system, and 30B shows the levels after the meander was developed. The average character of the water quality in the effluent is shown in Table 23. The heavy metals ratio as defined by the state of Missouri is an estimate of the efficiency of the overall system in treating this effluent. The heavy metals ratio is a ratio of the existing level of a particular heavy metal to that allowed by the state of Missouri. Figure 31 shows the decrease in heavy metals ratio as the waste passed through the meander treatment process. Figure 30C shows how the algae in the meanders effectively removes metals prior to effluent release. In addition, Figure 31 shows the average lead and zinc concentrations in the water of the meanders indicating their effective removal.

More up-to-date information on the performance of the passive effluent treatment system at the Buick Mine and Mill can be requested from:

MICHAEL KEARNE
Director, Safety, Health &
Environmental Services

Route KK
Boss, MO 65440
(314) 626-4211

It was concluded by JENNETT and WIXSON (1977) that levels of trace organics were reduced by the biological passive treatment system employed. The water treatment system at the Buick Mine-Mill-Smelter removed 87% of the trace organics in the raw effluent before treatment. By far the largest amount of trace organics were introduced in the mill where flotation reagents are used as opposed to the mine water.

SOURCE: WIXSON, ED. (1977)

JENNETT and WIXSON (1979) pointed out that although effective, biological treatment through the use of meanders for metals and organics removal, the long-term benefits to the environment would be naught unless a technology is developed on a timely basis to close the ponds out at the end of the operation in a way that fixes the metals. They felt that this aspect required research and development.

Additional information on passive biological polishing ponds and their design and performance at AMAX's Buick Mine in the New Lead Belt can be obatined from:

PASSIVE SYSTEM #4, NEW LEAD BELT, MISSOURI

(Former Arrangement - Now Changed)

Traditional practice in the mining industry has previously dictated that the mine and mill effluents be combined and treated in a single lagoon or tailings pond. This method was used over ten years ago in the New Lead Belt Region but did not work properly. Nuisance algal growth developed below mine-mill tailings pond effluent discharges in virtually every case where this was the sole method of treatment.

Faced with the problem of excessive algal blooms and their associated high levels of heavy metals and evidence that receiving stream water quality was declining as measured by the benthic diversity indices, the mining companies responded with changes in their waste treatment systems. It had been shown by WIXSON (Ed.) (1977) that the single tailings pond treatment systems commonly used by the industry to treat both mine and mill wastes simultaneously were insufficient to protect the streams of the Ozarks. Most mines treated their wastes by combining both mine and mill effluents for retention in very large deep ponds formed by building tailings stems across nearby valleys. Often considered a simple method of treatment, tailings ponds are deceptively complex because they are often required to perform a number of functions simultaneously.

Many treatment functions should take place in the tailings lagoon, including:

a. Removal of tailings solids by sedimentation.
b. Acid neutralization.
c. Formation of heavy metal precipitates.
d. Sedimentation of metal precipitates.

Figure 27. Diversity Index Values for Benthic Animals in Strother and Bee Fork Creeks, (Adapted from Ryck and Whitley).

e. Perpetual retuention of settled tailings and precipitates.
f. Stabilitzation of oxidizable constituents.
g. Balancing action for influent quality and quantity fluctuations.
h. Storm water storage and flow balancing.

The most critical of these functions are sedimentation of heavy metals and tailings, effluent stabilization, and ultimately, solids disposal.

In a design of a tailings pond, standard settling tests are of little value. Pond geometries are varied and cannot be reflected in standard settling tests. A detention time of 30 days is recommended by the Canadian Bureau of Mines with a minimum required detention time of 5 days. Some authors have suggested that the pond area should be 10 to 25 acres/1,000 tons (4-10 ha/1100 metric tons) of solids. In a study of tailings ponds of the New Lead Belt, it was found that those ponds, of at least 20 acres (8 ha) surface area and 5 to 15 feet (1.5 to 4.6 m) depth, were sufficient to remove the zinc content of mine and mill effluents. It was the settling velocity of these zinc particles which governed the pond size. Tailings ponds of smaller surface areas were efficient in removing lead and copper since these are generally denser minerals.

At St. Joe Minerals' Fletcher Mine and Mill, tailings decant water is recycled, and mine water was treated in a series of lagoons.

Recycling

In 1968, the Fletcher operations of the St. Joseph's Mineral Corporation in the New Lead Belt produced an effluent which was discharged into Bee Fork Stream with treatment by only a single tailings lagoon. Above the mine discharge, Bee Fork Stream was a typical clean Ozark Stream. There were usually seasonal blooms of algae, especially in the vicinity of springs. Below the confluence of the stream and mining effluent, a persistant mat-like biological community developed in the stream which, once established and without heavy storm activity to scour the stream bed, often reached problem levels. These dense algal mats trapped the fine silt material and heavy metals which then choked out benthic life.

In order to eliminate these problems, the St. Joe Minerals Corporation initiated a waste treatment system schematically shown below. It essentially treated the mine water in a series of five sedimentation ponds and recycled the mill water for reuse. Extra makeup water required at the mill came from the mine water and was included in the recycle loop. According to JENNETT and WIXSON (1977), heavy metals measured in the receiving stream declined precipitously since the multiple pond system was installed.

More recently, the minewater has been separately collected in a single 22-acre pond where suspended sediments are settled, and oil and grease trapped before discharge to the creek.

Figure 28. Fletcher Treatment System (Adapted from Gale, et al. (50))

Note: The System has now been completely changed and the above is shown as an interesting example only, rather than to describe the Operation.

In summary, the system as it exists today consists of a zero discharge mill and tailings system and a settled minewater discharge authorized by an NPDES permit.

Post Office Box A
Monaca, PA 15061
(412) 774-1020

In 1976, the Missouri Dept. of Conservations reported that the quality of the stream as measured by the Benthic Diversity Indices had returned to premining levels indicating that the system has been effective in controlling pollution.

PASSIVE SYSTEM #5: ST. JOE MINERALS, EDWARDS TAILINGS EFFLUENT, EDWARDS, NEW YORK

At ST. JOE MINERALS' Edwards Mill tailings decant system, tailings treated by lime addition are discharged into a large tailings pond separated by the tailings dam from a large swampy marsh into which the tailings dam decant solution discharges. Samples taken at a culvert about 2,000 feet downstream across this marshy bog indicate clearly that heavy metals values are polished in the marsh. In this case, the bog is natural. It is shallow with a wide variety of aquatic plants which seem to grow in a relatively evenly distributed fashion throughout the marsh providing good contact between water and plants. The data as observed by ST. JOE staff in 1974 are presented in the attached excerpt from a company internal report.

Further information is provided in the next chapter or can be requested from :

ST. JOE MINERALS COMPANY
Mining Division
Balmat, NY 13609
(315) 287-2500
J. G. (Mike) Reilly

PASSIVE SYSTEM #6: ST. JOE MINERALS PIERREPONT MINE

At ST. JOE MINERALS' new Pierrepont lead-zinc mine in upstate New York, minewater is discharged at 400 U.S. gpm (2,200 m^3/d) via a series of ponds which incorporate lime neutralization, settling, and polishing.

In all, 11 acres of ponds have been installed comprising:

Pond #1	2 Acres	Metal Precipitation and Settling:	Milky Appearance
Pond #2	3 Acres	Settling:	
Pond #3	6 Acres	Polishing:	0-6' Deep Bog
Total	11 Acres		

Regulatory Limits (New York State)

New York State has proposed new ultra-low metal water quality standards which, at the time of the RANDOL visit, still had not been approved but seemed well on their way to being so.

New York is an agreement state. Their RCRA and Clean Water Act regulations are administered by:

DEPT. OF ENVIRONMENTAL
CONSERVATION
Albany, NY

About 200 contaminants are included in the new proposed water quality limits, mostly chlorinated organics and the like which would not be expected in flotation mill tailings effluent, but the water quality limits for metals, as proposed, are potentially a serious problem for base metal mines.

Two general regulatory levels have been proposed for different classes of water in 6NYCRR Parts 701 and 702: For classes of water designated AA, A, A-S, B, C, and for D (fish passages). Metals levels for discharge to a trout stream designated Class C_T (i.e., suitable for fishing and swimming and for trout protection) into which the Pierrepont minewater is ultimately discharged, would meet the following standards:

EXAMPLES OF (NOVEMBER 84) FINAL NY STATE
PROPOSED WATER QUALITY STANDARDS mg/l (ppb)
CLASS C WATERS

Cu Max. = Exp (0.905 [ln Hardness ppm] - 1.785)
Fe Max. = 300 mg/l
Pb Max. = Exp (1.34 [ln Hardness ppm] - 5.245)
Zn Max. = 30 mg/l
Cd Max. = Exp (1.16 [ln Hardness ppm] - 6.14)

What these boil down to are the following maximum allowable limits at various hardnesses:

Hardness (ppm)	50	100	200
Cu Max. (ug/l)	5.8	11	20
Pb Max. (ug/l)	1	2.5	6.4
Zn Max. (ug/l)	30	30	30
Fe Max. (ug/l)	300	300	300

Meeting the proposed new regulatory limits will be very hard and, in some cases, virtually impossible to meet from a technical standpoint, let alone the cost factor.

A further existing regulation in New York specifies that for discharge to C_T class waters, i.e., a trout stream, allowable temperature increases are regulated. The warmer the water, the lower the amount by which the temperature can be raised. For example, if the stream water temperature is between 50-70°F, then the temperature can be raised no more than 2°F.

Biological Polishing

Pond #3 installed at Pierrepont is six acres in size and varies in depth from 1- 6 feet Pond depth can vary 2 feet with the season. An artificial meander has been established in the design of the pond.

The intention was to allow volunteer aquatic plants to grow in the pond which would act as a polishing media.

Performance

At the time o' the RANDOL visit, the composition of the mine effluent had still not reached a steady state, it being a new mine. A considerable amount of sulfide minerals were observed in the wasterock from which the roadways and pond walls had been constructed, and these may ultimately, on oxidizing, yield considerable amounts of AMD contaminants to the water. At the present inlet to the No. 1 pond, zinc values were 0.2 ppm soluble andd 0.3 ppm total zinc indicating that lime addition and biological polishing will be needed especially if the new New York effluent regulations are confirmed which would require Zn below 0.1 ppm water quality standard.

A problem for which no answer has yet been found lies in meeting the temperature limit during the hot summer months, although it would be expected that trout would be smart enough to move far enough up or downstream to make themselves comfortable during the hot days.

The #1 pond inlet was at 54°F.
The #1 pond discharge was at 70°F.
The #3 pond discharge was at 78°F.

Clearly, the ponding used to remove contaminants is causing the water to warm up to well beyond the regulatory limit for discharge to the stream. Being a small stream, it was considered likely that the warm effluent would have a major impact on the stream temperature which was already marginal as a trout habitat.

At the time of the visit in May, 1984, the aquatic plants had not yet become established in the pond to any marked extent. It was not known to what extent the shade and transpiration effects of the plants would cool the pond water in future, or how ST. JOE MINERALS would overcome this problem.

Edwards Tailings Effluent:
Effect of Passage Through a Portion of Cedar Lake "Swamp."

1. General

This test was undertaken in order to indicate the effect, if any, on the heavy metal content of the tailings effluent after having passed through a swampy area.

2. Location Features

After discharge from the Edwards Mill tailings pond, the water passes through a low-lying area (locally known as Cedar Lake Swamp). The so-called swamp is vegetated by trees, brush, clumps of grass, mosses, ferns, etc. Water passing through the area is caused to spread out because of minor ground relief due to tree roots, decaying logs, and frost pressure-ridges. Water appears to cover about half of the area and is several inches deep.

3. Sampling

The downstream sampling point selected was the culvert under the Trout Lake Road, about 1500 feet from the tailings pond overflow (see Map).

Daily grab samples were taken for five days, upstream (Tails) and downstream (Culvert), and each day's samples were analized for both "Total" and "Dissolved" heavy metals.

4. Results of Testing

4.1. Table 1. shows the five day averaged upstream and downstream values ("Total") as well as the 1973 averages for the Tails.

4.2. Table 2. shows the correlation between the "Total" and the "Dissolved" values, indicating that the metals were not filterable. (Filter media used was Gelman Type A with a DOP test rating of 0.3", 99.7%.)

TDS REMOVAL FROM TREATED AMD

In parts of the world there is concern about TDS in acid mine drainage, even after treatment. For example, conventional lime neutralization and the HDS process precipitates metals, but can result in a saturated gypsum effluent solution (somewhere around 2,000 mg $CaSO_4$ depending on temperature). NaOH precipitation of metals is more expensive in most cases because the cost of this reagent is higher than lime--by several hundred percent in some cases. Even so, the use of NaOH results in an equivalent increase in the sodium levels in effluents which, in some parts of the world (South Africa, for example), are also regulated.

HOLM and SIMPSON (1981), in their discussion on the removal of trace elements and acidity from the Argo Tunnel drainage near Denver, Colorado, indicate a "proposed water standard" which includes a maximum level of $SO_4^{=}$ at 250 mg/l. It is not known what the

basis for proposing this relatively low level of $SO_4^=$ is, but it is certainly clear that this would not be met by any conventional lime or sodium hydroxide precipitation process in treating most AMD streams.

The industrial and residential area known as Pretoria, Witwatersrand, Vereeniging, Sasolburg (PWVS) is served by the Vaal Dam through the Rand Water Board as the main regional water authority. The quality of this water supply is impacted by several industries of which the mining industry on the Witwatersrand is the most conspicuous. Due to the macro-recycle of water draining from the area into the Vaal Dam, TDS is building up to an extent that its impact has an annual cost to the economy in terms of enhanced corrosion, detergent use, etc. of several hundred million dollars. The likelihood of new regulatory limits on TDS in point source discharges has been indicated.

In order to reduce the TDS of acid mine drainage and/or treated acid mine drainage requires the use of desalination processes such as reverse osmosis, evaporation, ion exchange, electrodialysis, etc. Desalination processes were discussed in some detail in separate chapters of this report including some detail of a pilot scale demonstration of the new seeded slurry reverse osmosis process.

It is appropriate to mention three processes of interest where TDS levels must be reduced from AMD:

- The Alumina-Lime-Soda Process
- Seeded Slurry Reverse Osmosis
- Low Pressure Ultrafiltration with Charged Membranes

ALUMINA-LIME-SODA PROCESS

The alumina-lime-soda process has been shown to be able to reduce $SO_4^=$ concentrations to 250 ppm without difficulty through a two-stage process in which raw water is treated with sodium aluminate and lime to pH 12.0-12.1. Effluent from stage 1 is pH adjusted by adding CO_2 to pH 7.

The principles, performance, and economics of the alumina-lime-soda process are described by NEBGEN, et al. (1976) below.

Based on reactions for the process shown by the above authors, RANDOL fails to comprehend how the addition of sodium aluminate, lime, and CO_2 avoids buildup of sodium ions in the product solution as they claimed: "Since the sulfate anion is removed in the reaction, there is no net addition of sodium to the finished water as there is in conventional lime-soda ash softening."

More information and possibly updated economics analysis of the Alumina-Lime-Soda process may be possibly requested from:

Variations of the alumina-lime-soda process are described in two Russian papers.

PREDERII, et al. (1979) described a two-stage wastewater purification system developed to remove Cu^{2+} and $SO_4^{=}$ from copper mining wastewaters. In the first stage, the wastewater is stirred at 700 rpm with a $Ca(OH)_2$ suspension at pH 12.35 (the optimum condition). After settling, the clear liquor still contains up to 2,000 mg/l SO_4. In the second stage, the clear liquor was treated with $Al(OH)_5Cl$ and $Ca(OH)_2$ at pH 11.9 to precipitate $3CaO.Al_2O_3.3CaSO_4.31H_2O$. The clarified wastewater was then discharged. The neutralization step resulted in a precipitate of $CaSO_4$ containing entrained Cu and Zn. The precipitate, after drying, could be used as a metallurgical flux.

SAL'NIKOVA, et al. (1981) showed how Ca and SO_4 concentrations of tailings leachate were reduced from 800 and 2,140 mg/l to 180 and 300 mg/l respectively by precipitation with aluminous cement to give insoluble, non-toxic ettringite cement. The concentrations in minewater were reduced from 310 and 3,570 mg/l to 100 and 300 mg/l respectively. The smaller amounts of Cu, Fe, Zn, and Mg, which were present, were also reduced.

		Before Treatment	After Treatment
Mill Tailings Effluent	Ca	800	180 mg/l
	SO_4	2,140	300 mg/l
Minewater	Ca	310	100 mg/l
	SO_4	3,570	300 mg/l

Recovery of Potable Water from Acid Mine Drainage by the Alumina-Lime-Soda Process

J. W. NEBGEN, D. F. WEATHERMAN, M. VALENTINE, and E. P. SHEA
Midwest Research Institute, Kansas City, Missouri

In some parts of the country, particularly in Appalachia, water of potable quality is in short supply because of acid drainage from coal mining activities. The acid mine drainage can be converted into potable water by several desalination techniques, the usual ones being ion exchange or reverse osmosis. Such systems require a technology that is different from that used in conventional municipal water works, e.g., lime-soda ash softening. The alumina-lime-soda process, which is discussed in this paper, offers an alternative for recovering potable water from certain acid mine drainages without the need for sophisticated desalination procedures. Alumina-lime-soda is a chemical desalting process in which calcium sulfate derived from lime-neutralized acid mine drainage can be precipitated as calcium sulfoaluminate, thus yielding a product water in which sulfate concentrations are reduced to less than 250 mg/liter.

The key to the alumina-lime-soda process lies in the use of sodium aluminate as a treatment chemical. Sodium aluminate has long been known as an effective flocculating agent for turbid waters. In the case of the alumina-lime-soda process, however, the aluminate ion is a species onto which both calcium and sulfate ions can attach themselves and precipitate. In general, one mole of aluminate ion will remove about one mole of calcium sulfate. Since the sulfate anion is removed in the reaction, there is no net addition of sodium to the finished water as there is in conventional lime-soda ash softening.

For the particular case of acid mine drainage, alumina-lime-soda offers some other advantages, since the mine drainage usually contains dissolved iron and aluminum. The *in situ* aluminum can be converted to aluminate ion by adding excess lime to the mine drainage during neutralization. Aluminate ion so produced tends to remove calcium sulfate in a manner similar to that of sodium aluminate. Iron also tends to remove calcium sulfate as calcium sulfoferrite, though not as effectively as aluminum. Because the process operates on the alkaline side (*p*H of 12.0) and in the presence of air, all iron (II) is oxidized rapidly to iron (III) where it is readily removed from the system.

General details of the alumina-lime-soda process are discussed below, followed by application of the process to the acid mine drainage situation.

DESCRIPTION OF THE PROCESS

The principles of the alumina-lime-soda treatment are outlined in Fig. 1. The process operates in two stages. Stage 1 involves the treatment of raw water with sodium aluminate and lime. Effluent from the first stage is alkaline because of excess lime needed to maintain *p*H conditions. Thus, carbon dioxide at stage 2 is added to reduce *p*H and remove excess lime as calcium carbonate.

The chemistry of stage 1 involves the precipitation of a calcium sulfoaluminate at a *p*H of 12.0 to 12.1. The composition of the calcium sulfoaluminate is $2CaSO_4 \cdot Al_2O_3 \cdot 3CaO \cdot XH_2O$. Each mole of alumina added as sodium aluminate will precipitate 5 moles of calcium, 2 moles of which are as calcium sulfate and 3 moles as lime. This composition seems to be roughly a 50-50 mixture of two well-characterized calcium sulfoaluminates, $3CaSO_4 \cdot Al_2O_3 \cdot 3CaO \cdot 31H_2O$ and $CaSO_4 \cdot Al_2O_3 \cdot 3CaO \cdot 12H_2O$. Thus the purpose of sodium aluminate is the removal of both calcium cations and sulfate anions.

The lime removes magnesium and bicarbonate alkalinity. Magnesium is precipitated as the hydroxide, and bicarbonate precipitates as calcium carbonate. The process is capable of removing both carbonate and noncarbonate hardness in the raw water.

The lime also serves to maintain the *p*H of the stage 1 reaction at 12.0 to 12.1. This *p*H is necessary to produce the calcium sulfoaluminate having the composition $2CaSO_4 \cdot Al_2O_3 \cdot 3CaO \cdot XH_2O$. If the stage 1 *p*H is above or below the 12.0 to 12.1 range, smaller amounts of calcium sulfate are removed. This role of the lime appears to be associated with the equilibrium between aluminate ion (AlO_2^-) and aluminic acid ($HAlO_2$). The sulfoaluminate is precipitated by aluminate ion. Hence sufficient hydroxide (from the lime) must be present to shift the equilibrium towards

Fig. 1. Basic Scheme of the Alumina-Lime-Soda Process.

aluminate ion. We have found experimentally that the equilibrium conditions in the *p*H 12.0 to 12.1 is optimum for the process. The residence time needed for stage 1 is approximately 90 min.

Following stage 1 reactions, treated effluent is separated from the precipitated solids by filtration. The solids are microcrystalline and are readily dewatered using vacuum filtration or gravity filtration on sand. Dewatered solids can be safely disposed of in landfills since they contain no noxious materials. About 98% of the treated water is recovered in the stage 1 effluent.

The stage 1 effluent is alkaline, containing about 600 mg/liter causticity as $CaCO_3$. The causticity is removed together with residual hardness by carbon dioxide neutralization in stage 2 of the process. The

Effluent from stage 1 thus contains 100 mg/liter of sulfate along with 600 mg/liter of causticity as excess lime. In order to bring down the *p*H and remove the lime, carbon dioxide is added in the second stage. This chemistry is straightforward, and no difficulties were encountered in the field studies. The important consideration in stage 2 is to keep the carbonation to a minimum in order to prevent resolubilization of calcium carbonate as calcium bicarbonate. Thus, the stage 1 effluent should be carbonated to a *p*H of 10.3, the point of minimum solubility of calcium carbonate. At this point, the *p*H 10.3 aqueous phase is separated from the calcium carbonate solids, and a little more CO_2 can be added to drop the *p*H to near 7.0.

Because the sulfate level in stage 1 effluent is 100 mg/liter, raw acid mine drainage can be used to neutralize a part of the stage 1 effluent rather than carbon dioxide. The amount of raw acid added at this point can be determined by the level of sulfate desired in the final product water. This partial neutralization can result in significant savings for CO_2 costs in stage 2.

CHEMICAL COSTS OF THE ALUMINA-LIME-SODA

Chemical costs of the alumina-lime-soda process hinge upon the cost and availability of sodium aluminate. The July 1975 price of dry sodium aluminate is $245.00/metric ton ($270.00/ton). Thus the current sodium aluminate price is $0.176/kg ($0.135/lb.) on a bulk basis. Liquid sodium aluminate costs $0.194/kg ($0.088/lb.) on an 18,000-kg (40,000-lb.) basis. When converted to a dry basis, the cost equivalent today of sodium aluminate is about $0.44/kg ($0.20/lb.), rendering liquid sodium aluminate noncompetitive with the solid in full-scale plant operations. Thus, liquid sodium aluminate was not considered in cost estimations.

If a number of alumina-lime-soda plants using mine drainage with sulfate concentrations in the 1,100- to 1,200-mg/liter range totaling 19 million liters (5 million gal.)/day were built, one would need approximately 5,500 to 7,300 metric tons (6,000 to 8,000 tons)/year of dry sodium aluminate. If the

*Raw AMD data from present study.

alumina-lime-soda process were applied to areas having other kinds of problems, e.g., high calcium sulfate waters in the western states, the demand for sodium aluminate would increase further. This quantity represents about a 50% increase in the demand for the chemical. In addition, high grade sodium aluminate would not be required. Thus, it is likely that the price would drop substantially by the time the process is developed to full scale.

An alternative approach to sodium aluminate would be its manufacture by calcining bauxite and soda ash, rather than by its crystallization from sodium aluminate solution. Process principles are almost identical with those associated with Portland cement manufacture, except that the temperature of the rotary kiln is in the 900 to 1,100°C (1,650 to 2,000°F) range rather than in the 1,300 to 1,500°C (2,350 to 2,700°F) range. Approximate composition range of sodium aluminate produced from calcining bauxite-soda ash mixtures will be: Na_2O, 37 to 40%; Al_2O_3, 52 to 54%; and SiO_2, 5 to 7%.

Sodium aluminate produced by the calcination of bauxite and soda ash would be less pure than that presently produced commercially. Bauxite contains siliceous impurities that result in the formation of sodium silicate as well as sodium aluminate. However, the soda fraction of the sodium silicate is useful in the alumina-lime-soda process, so its presence is not detrimental. The silica will be precipitated in the sludge and not appear in the product water. The important constituent in the product is the sodium aluminate, since the alumina fraction is all important for sulfate removal.

The calcining of sodium carbonate and bauxite is a straight line process closely resembling the manufacturing process for cement. The same general types of equipment used in cement manufacturing are needed for calcining soda ash and bauxite to yield sodium aluminate, carbon dioxide, and water. The general types of equipment are: crushing, grinding, rotary kiln, and conveying and handling.

The selling price of sodium aluminate (85% purity) is estimated to be \$0.176/kg (\$0.08/lb.). This price compares to aluminate produced as a specialty product (72% purity) of \$0.298/kg (\$0.135/lb.).

Tables 2 and 3 are estimated chemical costs for treating the two raw mine drainages studied to sulfate levels of 250 mg/liter. The costs are based on two kinds

Hydrated Lime, 93% $Ca(OH)_2$	13.17	0.26	13.03	0.26
Total Chemical Costs (\$/1,000 gal.)		0.91		0.61

of sodium aluminate—"dry" sodium aluminate that is available commercially, and "calcined" sodium aluminate that is manufactured by heating a soda ash-bauxite mixture to 1,000°C (1,832°F). Dry sodium aluminate contains water of crystallization and hence contains less active alumina than does calcined. As can be seen from the tables, the use of the calcined sodium aluminate is preferred because of its lower cost.

The chemical costs have been calculated using the following bases:

Chemical	*Cost ($/kg)*	*Cost ($/lb.)*
Dry sodium aluminate	0.298	0.135
Calcined sodium aluminate	0.176	0.080
Hydrated lime, 93%	0.044	0.020
Carbon dioxide	0.110	0.050

Using the calcined sodium aluminate, the chemical costs for a mine drainage of low acidity (Proctor No. 1) are about $0.074 per 1,000 gal., and those for a somewhat stronger mine drainage (Proctor No. 2) are $0.61 per 1,000 gal. It is unlikely that the Proctor No. 1 drainage would be treated by alumina-lime-soda, since only 25% of the volume needs to be treated to drop the sulfate level in product water from 300 to 250 mg/liter. In this case, conventional neutralization would bring this water very nearly to potable standards.

On the other hand, 80% of the Proctor No. 2 drainage is treated to bring sulfate levels from 750 to 250 mg/liter at a cost of $0.61/1,000 gal. product water. When operating costs are added to the chemical costs, it is estimated that total water recovery costs will range from $1.04/1,000 gal. in a 0.5 MGD plant to $0.79/1,000 gal. in a 5.0 MGD plant. Thus, the alumina-lime-soda water recovery costs are competitive with other processes for recovering potable water from acid mine drainage.

ACKNOWLEDGMENTS

Results reported in this presentation were obtained under the Commonwealth of Pennsylvania Service Contract No. EER-116, under a grant (No. S-802816) from the U. S. Environmental Protection Agency. Environmental Protection Agency, Crown Mine Drainage Control Field Site, Rivesville, West Virginia.

SEEDED SLURRY REVERSE OSMOSIS/EVAPORATION

Seeded slurry reverse osmosis is discussed in greater detail in the chapter on reverse osmosis desalination and in a trip report on East Rand Proprietory Mines Ltd. in Appendix I.

Although demonstrated only at 5 m^3/d, the results are sufficiently encouraging to allow speculation that if a desalination process is to find an application, this one is the most likely to be useful.

A flow diagram of the 5 m^3/d test unit and also for a 10,000 m^3/d plant are shown below.

Seeded slurry R.O. employs tubular R.O. modules through which a seed slurry of precipitated solids is recirculated with the feed solution. In this manner, a feed solution approaching gypsum saturation can be fed to the unit and a desalinated product recovery achieved up to 95% or more without the concentrate fouling the membrane despite total salt levels in the concentrate reaching many times saturation level. This is because as the concentrate exceeds saturation point, salts precipitate out on the slurry solids rather than on the membrane.

The R.O. modules installed in the test plant were operated at 4,000 kPa or 600 psi.

By employing the seeded slurry recycle concept, applicability and water quality conditions have been shown to be dramatically extended allowing for a greatly improved operating range.

The seeded slurry R.O. and evaporation process was described by REAMS GOODLOE (1984) at the RANDOL Workshop on Water Management and Water Treatment Technology which is inserted in the chapter on Desalination.

OPERATING LIMITS FOR R.O. MODULES

Composition of Concentrate	Conventional R. O.	Seeded Slurry	
		Feed	Conc.
Mn	0.1 ppm max	8.4	69 ppm
Fe	0.1 ppm max	6.4	100 ppm
Al	low	280	
Heavy Metals	very low for metals that precipitate e.g. Co, Ni, Sr, Ba		
Sr	very low	40	
Ni	very low	8.0	
Co	very low	2.0	
Silica	160 ppm in reject	No limit	
$CaSO_4$ in reject	1.5-2 times solubility (around 3000 ppm)	No limit	

An interesting set of data was obtained for one application of SRO. It is believed that the data reflects acid mine drainage water treatment by SRO in a situation analagous to ERPM.

DISCUSSION SRO

1. Seeded slurry R. O. as demonstrated by RCC represents a major breakthrough in desalination technology in that membrane fouling is avoided even when recovery is increased to a point where the concentration levels of gypsum in the reject rise to many times saturation which would result in fouling in the conventional application of R. O.

2. Slurry seed is kept in the dihydrate gypsum form for recycling. This is controlled by temperature.

3. A second major advantage of seeded slurry R. O. is that the compact concentrate slurry has a high solids content, i.e., it is compact and less costly to dispose of safely. One way would be to take the SRO reject and recover more water by evaporation resulting in a dry solid waste for disposal. Another would be to mix the reject with a pozzolin to make a pozzolinic waste for landfill disposal. Typical pozzolins would be cement, or power plant flyash.

4. In the recycle flow the concentration of calcium reaches about 440 ppm which is not much more than the level of 330 ppm Ca in the feed solution. This is because calcium is removed from solution by the seed crystals.

5. Silica and alumina levels are also effectively controlled by the seed slurry. A typical slurry seed contains 5% SiO_2.

6. Because the seed slurry contains solids, it would be expected that there could be abrasion damage to the membrane surfaces. This does not, however, appear to occur.

7. Abrasion of pump impellers etc. could be expected but has not been apparent. In the ERPM test unit, however, some abrasion of the choke valve at the end of the pressure system is believed to have occurred. In a full scale system a different pressure maintaining system would be used. e.g., an orifice plate. It is not known to what extent abrasion will be a problem here.

8. It is expected and hoped that the ERPM tests will proceed using larger scale plants and that their data and experience will be released to industry for general use.

LOW PRESSURE ULTRAFILTRATION WITH CHARGED MEMBRANES

BHATTACHARYYA, DIBAKAR; GRIEVES, ROBERT B.; SHELTON, SHEILA (1979) reported on tests of low-pressure ultrafiltration with negatively charged, noncellulosic membranes which were shown to be a feasible process to remove dissolved metals (and sulfate) and suspended solids from acid mine drainage. The process achieves "good" water flux without membrane fouling and adequate ultrafiltrate quality at a high recovery. The authors compared the ultrafiltration results with reported results for lime precipitation, settling, and reverse osmosis treatment field studies in terms of treated water quality, reusability, concentrate (sludge) production rates, water recovery, and membrane flux behavior. Unlike the lime precipitation and settling process, the low pressure ultrafiltration product water is not saturated with gypsum.

Possibly, more information on this process and on any more recent developments may be obtainable from:

NOTE

This report is based on information provided by literally hundreds of individuals in mining, engineering, and consulting companies. The author gratefully acknowledges this industry support without which RANDOL surveys would not be possible.

The information contained herein is submitted on a "best efforts" basis. Although an attempt has been made to avoid misleading errors, this report should be used by sponsors at their own risk and subject to verification. Since it deals with a pioneering field, it has not been altogether possible to avoid speculative assessments.

Some of the information may possibly be "sensitive." This report is submitted to you on condition that sponsors hold its contents strictly confidential.

STANDARD TREATMENTS

Standard treatment practice for effluents might include the following. This classification is subject to debate and is made on a tentative basis:

Process	Removal of
1) Lime Precipitation and Settling	: Fe, Mn, Cu, Pb, Zn, Cd, Ni
2) Precipitation as Ferroarsenate	: As
3) Aging and Oxidation	: Thiosalts and Thiosulfate
4) Ion Exchange	: Uranium, Molybdenum
5) Coprecipitation with $BaSO_4$	: Radium
6) Alkaline Chlorination	: Cyanide, Ammonia
7) Natural Degradation	: Cyanidation Effluents

The "standard" treatment practices often work well but can be subject to climatic constraints and other limitations. In several cases, their performance is inadequate to remove contaminants to the levels required to render effluents "non-toxic" and to meet some proposed and even existing regulatory requirements. Even the way the "standard" techniques are applied varies significantly from company to company and even within a mining company and from site to site. The previous chapter on acid mine drainage

treatment discussed some observations made in visits to effluent treatment plants. This chapter includes items reported in the literature and identifies some of the new and innovative technologies that are in the experimental and development stages. Often, available information was scanty, and the reader is again cautioned to regard comments and observations as a guide requiring confirmatory testing in all cases for any specific application.

SIX CARDINAL RULES

Sponsors are urged never to lose sight of the six cardinal rules for process selection and design which will be appropriate for most mining and milling environments:

1) Look at the needs of a problem using a circumspectual systems approach. Whatever is treated may have a side effect, either beneficial or detrimental, present or future. The need to treat an effluent may perhaps be alleviated altogether by recycling.

2) Prevention is better than cure. Appropriate design at the outset can greatly reduce the volume of effluent to be treated and, in some cases, avoid the need for perpetual treatment and maintenance after the operation closes down.

3) Use available abatement assets - e.g., natural attenuation qualities of soil or subterrain; residence time in the tailings dam or reclaim solution pond; or a biological polishing pond.

4) Avoid sensitive, sophisticated high technologies wherever possible. Keep the process simple, flexible, and "operator proof."

5) Reliability is essential where effluents are treated before discharge to sensitive environments, particularly streams and lakes supporting fisheries. One failure event can do as much damage as not having the installation at all. Provision is needed in such cases for continuous on-line monitoring and a means of impounding and returning effluents that do not meet the discharge criteria.

6) Design for maximum flow and load, not the average requirement.

OTHER TREATMENT AND POLISHING PROCESSES

Numerous other processes have been employed for the treatment or polishing of acid mine drainage and other effluents or have potential future applications. Several of these are discussed in later chapters where removal of individual metals are discussed. Some of these technologies are still in the developmental stages for AMD treatment yet may have

some potential for special cases. Some of these are definitely in the category of frontier technologies and are included in this discussion only as a means of documenting the people and factors involved.

- Recovery of Values by Selective Precipitation
- Recovery of Values Using IX
- Desalination of AMD Using CIX
- Sulfide Precipitation of Metals
- Metal Removal by Insoluble Starch Xanthates/Cellulose Xanthates
- Chelation for Metal Removal
- Liquid-Filled Membranes
- Biological Oxidation of Ferrous to Ferric
- Biological Sulphate Removal
- Biological Metal Removal Process
- Agricultural Waste Products for Metal Removal and pH Adjustment

RECOVERY OF VALUES USING SELECTIVE PRECIPITATION

Several AMD effluents contain a range of metals which in the past have been considered for potential resource recovery. This possibility was closer to reality, perhaps, just after the OPEC oil crisis when metal prices all rose to new highs, cobalt in particular.

The effluents from several South African gold and uranium mines contained copper, nickel, cobalt, and manganese values.

Several years ago a chemistry approach using selective precipitation was devised to separate and recover at least cobalt and manganese, the latter in a suitable form to be a raw material for electrolytic manganese production. This was described in a paper, and more information could be requested from Max Harris, one of the authors, or Dr. Philip Lloyd who drew RANDOL's attention to the potential.

Years ago Max Harris, in conjunction with a subsidiary of GENCOR LTD. (then GENERAL MINING AND FINANCE CORP.), operated a manganese recovery plant treating gold-uranium mill effluents. Since then, he has found it more economic to use manganese ore, however, and the old manganese production near Krugersdorp, Transvaal, has shut down.

At current base metal and cobalt prices, the incentive to try and recover metals from such effluents has greatly diminished.

JANKE, DENNIS, and DIEBOLD, FRANK E. (1983) tested selective precipitation of Al, Ca, Cu, Fe, Mg, Mn, Ni, Si, and Zn from acid minewater from mining of porphyry copper ore. Lab scale experiments were made with and without the addition of an oxidizing agent and $S^{=}$. The potential recovery by selective precipitation was estimated to be 85% plus for sulfide precipitation selectively of copper and zinc as sulfides and hydroxides of Fe, Al, Mn, and Mg. The titraton endpoint is optionally determined by measurement of the specific electrical conductance and ionic strength.

The authors are located at Butte, Montana, 59701, where they are employed by the MONTANA APPLIED RESEARCH GROUP.

RECOVERY OF VALUES USING IX

Several ion exchange applications are used to treat mine and mill effluents to render these suitable for discharge and/or to recover metal values. There appear to be additional opportunities in this direction, and the literature is full of reported applications, often on bench scale; it is difficult to sort out which are of practical value.

Examples of existing operations that come to mind are:

1) U_3O_8 recovery, QUIVIRA MINING COMPANY, Grants, New Mexico.

2) U_3O_8 recovery, COTTER CORP., Schwarzwalder Mine, Golden, Colorado.

3) U_3O_8 recovery, DENISON MINES, Elliott Lake, Ontario.

4) Copper recovery, El Teniente, Chile.

5) Molybdenum recovery, Climax Molybdenum Division of CLIMAX, Colorado.

In each of the above cases except the last, a valuable resource is recovered. In the case of Climax Molybdenum, economics did not justify the recovery of molybdenum values from the eluate.

QUIVIRA MINING CO., AMBROSIA LAKE, NEW MEXICO

Seepage and minewater pumped from underground stopes of the QUIVIRA MINING COMPANY's Ambrosia Lake operations near Grants, New Mexico, contain 10-12 ppm U_3O_8. Uranium is removed from this water by ion exchange, and radium is precipitated using $BaCl_2$ prior to discharge.

Macro recycling of water and seepage from the tailings dam into the underground workings of mines located close by have resulted in a steady buildup of competing ions with the result that the metallurgical efficiency of the simple two-stage continuous ion exchange system has deteriorated over the last several years. For these solutions, a more sophisticated multiple-stage continuous ion exchange system such as the NIMCIX system developed in South Africa would be required to bring the tailing level of uranium down. More details of the QUIVIRA MINING COMPANY CIX system are included in the trip report in Appendix I or may be requested from:

QUIVIRA MINING COMPANY
Post Office Box 218
Grants, New Mexico
(505) 287-8851
Jonathan Ma, Metallurgical Manager

The best way to remove uranium from minewater is to use the water in the mill and to recover the uranium in the process. In this case, the volume of water that must be pumped from the mines is far in excess of that needed by the mills. Also, NPDES permits can be granted to discharge treated minewater which is not permitted for mill tailings decant solution which has to be evaporated rather than discharged in net evaporation sites such as in New Mexico where "zero discharge" is mandated.

U_3O_8 RECOVERY, COTTER CORPORATION, GOLDEN, COLORADO

At the COTTER CORPORATION's Schwarzwalder Mine, Golden, Colorado, uranium is recovered from a 520 U.S. gpm flow of minewater which arrives at the treatment plant at pH 7.5-7.8. Uranium is removed from this minewater containing 3-3.5 ppm U_3O_8 to an effluent level of 10-20 ppb using an innovative Himsley-designed downflow continuous ion exchange system.

This uranium recovery system is described in greater detail in a trip report titled COTTER CORPORATION in Appendix I, by PALMER and HIMSLEY (1984) and HIMSLEY

and BENNETT (1984). Uranium is eluted from the resin to yield a very small volume of eluate containing 10-15 g U_3O_8/l which is shipped to the COTTER CORPORATION's mill at Canon City, Colorado, where it is inserted into the uranium recovery process. The remarkable aspect of this operation is that a fixed bed ion exchange process can achieve such phenomenal results.

The ideal solution to minewater containing uranium is to use it in the mill as process water but in this case, the mill is remote from the mine, and the water must be discharged as an effluent.

URANIUM RECOVERY, DENISON MINES LTD., ELLIOTT LAKE

Minewater from underground workings at Elliott Lake is acidic due to oxidation of sulfides, and it contains some uranium. This minewater must be treated before it can be discharged. DENISON MINES LTD. has resolved to make it worthwhile to treat this minewater by using it to leach as much uranium as possible from the stopes before pumping it to the surface. Not much is known about how DENISON applies this form of in situ leaching except that acidic water is sprayed over certain stopes and then collected for pumping to the surface where the uranium solution is blended into the mill solution which allows uranium to be recovered before the water is discharged with the tailings.

COPPER RECOVERY, EL TENIENTE MINE WATER, PERU

In 1984, a new solvent extraction plant was started up to recover copper from minewater at the El Teniente Mine.

	Aqueous Flow Rate	Copper Production
Minimum	250 m^3/h	Less than 1,000 Tons/Year
Nominal	612 m^3/h	4,060 Tons/Year
Maximum	900 m^3/h	4,611 Tons/Year

At nominal flow rates and below, the plant operates in a conventional counter-current, two-extraction, two-strip mode. For higher flowrates, the plant can operate with the

aqueous feed in parallel through extraction. The flow is seasonal and coincides with the spring snow melt. High copper tenors of 2 g Cu/l and more often coincide with high flows at the beginning of the runoff.

More information can be obtained from the company that designed and installed the copper recovery plant:

MOLYBDENUM RECOVERY, CLIMAX, COLORADO

At Climax, Colorado, AMAX, INC. has installed a water treatment plant to remove contaminants including molybdenum from decant solution from the Climax Molybdenum tailings pond system prior to discharge to the creek system that flows into the Denver water supply.

Installation of a plug flow Chemseps continuous ion exchange unit is capable of reducing molybdenum from 2.0-20.0 mg/l to around 1.0 ppm or less in effluent as described by GOTT and LAFERTY (1977).

The system used weak-base amine type anion exchange resins for two reasons: 1) the molybdenum adsorption capacities were greater; and 2) the resin's high affinity for the hydroxyl ion allows for effective elution with smaller alkaline requirements. The resin was regenerated using sulfuric acid, not only because of its lower cost, but also to avoid contamination of the effluent water with chloride ions.

When the CIX plant was first operated, there were several mechanical problems which resulted from the attempt to operate at a too ambitious specific flow rate recommended by the designers. This led to internal screen failures.

Meanwhile, AMAX has found alternative ways to remove molybdenum from their tailings effluent, and subsequently a way has been found to meet their effluent discharge regulations without the need for molybdenum removal using the CIX system.

Even when the CIX plant was operated, it was found to be non-economical to recover the molybdenum values.

ION EXCHANGE PROCESSES - EXAMPLES

KENNEDY, et al. (1984) reported on the development of an ion exchange process for recovery of cobalt and nickel from primary lead smelter residues. One of the authors, A. A. Worcester, is employed by ST. JOE MINERALS.

CHOPRA (1984) provided an update of the Chem-Seps continuous ion exchange system for pollution control, and SLATER, et al. (1978) showed the results of a continuous CIX unit to treat a synthetic minewater containing 56 ppm Cu, 3.5 ppm Ni, 0.3 ppm Co, 1 ppm Fe, and 20 ppm Ca at pH 4 using a bed of strong acid resin Amberlite 200D in the sodium form which was eluted using saturated NaCl.

MORAWE (1984) showed how ion exchange can be used to remove fluorides from aqueous solutions which could possibly be useful for treatment of high fluoride mine waters as occur in some parts of the world.

Several consultants and authors have pointed out how soils and bedrock can attenuate the migration of metal species by natural processes including the ion exchange properties of the underlying materials which is a form of ion exchange of a sort.

CRONCE, et al. (1980) discussed the effect of lime and unlimed soils on the acid coal mine drainage and concluded that some soils, after liming, remain relatively unchanged even after considerable quantities of water have been applied. Where acid mine drainage was irrigated, growth of ryegrass and tall fescue was not adversely affected although it was significantly increased by liming and by increased levels of acid water irrigation.

WILMOTH, et al. (1979) compared the effectiveness of lime neutralization, reverse osmosis, and ion exchange for their effectiveness in removing ppm levels of ten trace elements from acid mine drainage under typical field conditions. The metals tested were As, B, Cd, Cr, Cu, Hg, Ni,P, Se, and Zn. Treatment by lime neutralization was very effective in removing As, Cd, Cu, Ni, and Zn and relatively ineffective in rejecting B.

The two-bed (strong acid-weak base) ion exchange system was very affective in removing all the trace elements except P and B. None of the treatment methods was effective in removing P.

McGARVEY and UNGAR (1980) describe some selective ion exchange resins for metal recovery which could be useful in selective resource recovery from some AMD streams, although the IX systems and economics would have to be taken into consideration.

DESALINATION OF AMD USING CIX

One of the problems associated with the use of ion exchange in desalination or contaminant removal from effluents is that in order to regenerate the system, more chemicals must be added to the system. This ultimately leads to the need to dispose of still more salts in the final concentrate than were in the water to start with.

HENDRY (1982) described a continuous counter current ion exchange CCIX process which was developed at the University of Cape Town for desalination of mineralized effluents and brackish water. The process utilizes macroporous resins in a strong cation/weak anion sequence. Removal of organic matter by the anion resin results in color and odor removal and about 70% reduction of the COD of humus tank effluent.

No pretreatment is required, and resin has been in use over the equivalent of more than two years of continuous operation without significant fouling or loss of capacity. The author claims that any required degree of desalination is attainable. The basic four-column system (cation load and regeneration pair and anion load and regeneration pair) of counter current fluidized bed multi-stage contactors attain greater than 80% water recovery using up to 1.0 N sulfuric acid and 0.2 N lime slurry as regenerants. Low solubility of $CaSO_4$ in the cation waste liquid and column operating problems if high lime concentrations are used set limits on water recovery. The calcium content of the feed water affects water recovery.

New techniques using a five-column system permits by-product recovery and/or reuse of spent regenerants and result in over 90% water recovery. Capital cost estimates for a 10,000 m^3/d plant are R5 million (US$2.5 million), and operating costs are R0.30-R0.40/m^3 for removal of 500 ppm TDS. More recent work involves contacting the resin with a lime slurry to generate a gypsum slurry which could be elutriated from the regeneration column and evaluation of carbon adsorption polishing of the ion exchange product to produce potable water.

This process has not come to the forefront in South Africa for the treatment of acid mine drainage. One problem is the complexity of operating a five-column CIX system. The

CCIX process may yet be improved further to become a contender for the emerging desalination market in South Africa.

SIROTHERM

A second continuous ion exchange process for desalting brackish underground and surface waters is the Australian Sirotherm process described by BALTO (1975) and BALTO, et al. (1982). In the first paper it was reported that problems of synthesizing polymers with adequate thermally regenerable capacity and rates of salt uptake were overcome. Pilot plant trials were claimed to have confirmed a technically feasible and economically viable process.

The major CSIRO contribution to ion exchange technology has been the invention of resin systems which can be regenerated by washing them with hot water. Sirotherm resins are polymers of the weak electrolyte type which must always be employed as a mixture of polymers containing basic and acid groups. The sites for adsorption of ions are formed from the uncharged groups by transfer of protons from the acidic to the basic species:

$$R'CO_2H + R''NR_2 + Na^+ + Cl^- \underset{\text{Hot}}{\overset{\text{Cold}}{\rightleftharpoons}} R'CO_2^-Na^+ + R''NR_2H^+Cl^-$$

The overall equilibrium is temperature sensitive with the uncharged forms of the resins being favored at higher temperatures. The driving force behind the equilibrium is the large increase in the ionization of water that occurs on heating--about 30 fold from 25° to 85°C. The additional protons and hydroxyl ions suppress the ionization of the weak electrolyte resins.

A major effort has been made to develop the Sirotherm process into a useful desalination tool. A magnetic microbead resin product was developed and is marketed by ICI AUSTRALIA LTD., which exhibit very interesting hydraulic properties which could possibly be applied to ion exchange systems beyond Sirotherm. CSIRO has developed continuous multi-stage adsorption and regeneration contactors.

The Sirotherm system has been demonstrated on a commercial scale for primary desalination of boiler feed at an ICI soda ash plant at Osborne near Adelaide, Australia. A 1,000 m^3/d demonstration continuous plant has been installed to remove NaCl from softened municipal wellwater at Leaderville, East Perth.

CONCLUSIONS ON SIROTHERM FOR AMD DESALINATION

1) Most AMD dissolved salts consist of sulfate, metal ions, Fe, Cu, Pb, Zn, and after treatment with lime, metal salt concentrations decrease, but Ca values increase.

   Consequently, the Sirotherm process, which is designed for NaCl removal, is not applicable to most AMD desalination needs.

2) Recovery of water product by Sirotherm is around 85% which leaves a large volume (15% of feed volume) to be disposed of as a concentrate.

More information on the Sirotherm process resins and applicability would be available from:

UNIVERSITY OF CALIFORNIA - SALINE WATER CONVERSION

The University of California has conducted intensive research on nearly every aspect of water desalination for nearly 30 years. The group working on ion exchange is located at the University of California at Berkeley under Gerhard Klein as manager, Theodore Vermeulen and Clayton Radke as faculty participants, and Jelena Sinkovic as staff. The Sorption Processes Group investigates purification and separation problems insoluble by conventional methods of water treatment.

This group favors ion exchange over other types of feedwater pretreatment for desalination based on the group's past and current work on alkalinity reduction and scale prevention showing that ion exchange gives more secure process control at a lower overall cost. Such studies have enabled the state's agricultural wastewater desalting demonstration plant to utilize reverse osmosis on high-sulfate waters without risk of fouling. The feedwater being freed from calcium, the reject brine is low enough in calcium to regenerate the ion-exchanger without any purchase of chemicals.

Although no specific IX processes have been mentioned specifically for AMD treatment, the University of California pool of fundamental ion exchange experience may be of some help in evaluating IX problems.

SULFIDE PRECIPITATION

Sulfide precipitation offers several advantages over lime precipitation. To date, sulfide precipitation is not routinely used for the removal of metals from AMD although it is used in many metal plating operations, and it is also used for purification of electrolyte in the manufacture of electrolytic manganese as described in the trip report on Delta Manganese in Appendix I.

One aspect that requires careful consideration is the disposal of sulfide sludges. Preliminary studies have indicated that metal ion leachability is lower for metal sulfide sludges than for hydroxide sludges. However, the long-term impacts of weathering and bacterial or air oxidation have not yet been evaluated. Necessary precautions for environmentally safe disposal of sulfide sludge have not been established.

It would appear that sulfide precipitation may offer a more powerful polishing step in conjunction with lime precipitation and HDS or even limestone treatment of AMD, but this has yet to be demonstrated on a large scale application, although LARSEN and ROSS (1976) demonstrated a two-stage sulfide polishing process acid mine drainage treatment in Colorado with apparent success.

There also appears to be a useful biological polishing potential in which the anaerobic deeper levels of bogs or marshes yield adequate H_2S or FeS through bacterial reduction of sulfate ions or plant-derived organic sulfur to polish solutions without the need to add sulfide. This, in fact, seems to be one of nature's cleansing mechanisms.

To date, the only location where a sulfide precipitation application was encountered in a mining environment was at COMINCO LTD.'s Con Mine at Yellowknife, Northwest Territory. Reference to the COMINCO addition of NaHS and $FeSO_4$ to a gold mill tailings effluent is made in a trip report included in Appendix I. In this case, the sulfide precipitation of metals is effective even in decomposing metal cyanide complexes.

The Sulfex process which uses the addition of freshly prepared FeS rather than direct addition of sodium sulfide or sodium hydrosulfide. The Sulfex patent is assigned to:

Additional information on sulfide precipitation is included in the following references:

BHATTACHARYYA, D., JUMAWAN, A.B., and GRIEVES, R.B. (1979) Separation of Toxic Heavy Metals by Sulfide Precipitation Separation. Science and Technology 14(5), pp441-452. Sulfide precipitation of a synthetic solution containing As, Se, Cd, Zn, Pb, and SO_4 found that at low sulfide dosages, As and Se were removed due to coprecipitation on the other metal hydroxide precipitates at pH 8.5.

SCOTT, M.C. (1979) Sulfide Process Removes Metals, Produces Disposable Sludge. Industrial Wastes, July/August 1979.

YELIGAR, M.B., BAGENSICI, G., and SCHLAUCH, R.M. (1981) Treatment of Metal Finishing Wastes by Use of Ferrous Sulfide. EPA Project Summary EPA-600/S2-81-142, September 1981. This describes a demonstration plant to evaluate performance and costs of the SULFEX process at the Holly Carburetor Company, Paris, Indiana. It was pointed out that where more than one flow is to be treated or where variation in metal content

occurs from time to time, it is essential to insert an equalization tank to dampen fluctuations in wastewater flow and metal concentrations into the reactor-settler unit.

In their tests, the best removals of As and Se were obtained from synthetic solutions at a post-precipitation pH of 5.0 to 5.5 and at a sulfide dosage of 0.3 mM. For waters containing moderate to high concentrations of Fe, the arsenic removal was considerably higher as in the case for actual wastewater from a copper smelter scrubber from which at a sulfide dosage of 5.0 mM and a final operating pH of 8.0-8.5, removals of Cd, Zn, and Cu were greater than 99%, and As and Se removals were 98 and over 92% respectively. Arsenic and selenium removals were primarily due to adsorption on precipitates.

INSOLUBLE STARCH XANTHATES/CELLULOSE XANTHATE

No commercial-scale use of insoluble starch xanthates or cellulose zanthate for removal of metals from mine or mill effluents was identified. Nevertheless, encouraging results in the use of these materials in the treatment of plating wastes makes it worth mentioning this technology for consideration if and when particularly difficult levels of metals must be removed, perhaps to fulfill the needs of a special situation.

Insoluble starch xanthate was developed for application in the removal of metals from dilute solutions by the U.S. Dept. of Agriculture:

U.S. DEPT. OF AGRICULTURE
Northern Regional Research Center
Peoria, IL 61604
(309) 685-4011
R. E. Wing

Insoluble starch xanthate is used, according to WING (1983), in doses of around 0.154 g/l, i.e., 0.30 lb. per ton water (0.154 Kg/m^3).

Insoluble starch xanthate is manufactured by:

POLLUTION TECHNOLOGY SYSTEMS
2922 Benton Street
Garland, TX 75042
(214) 272-4010
Dale MacFeeters, President
Michael Coward

The price of insoluble starch xanthate is around $1.80/lb, and it is intended by the makers for use in the polishing of solutions rather than for primary treatment. The same manufacturer makes a dithiocarbamate product X-2000 which is intended for primary treatment. Cost of this product is $8/gallon.

Two-stage process chemically treats mine drainage to remove dissolved metals

Fig. 1—Field treatment system for mine drainage

H. Peter Larsen and Laurence W. Ross, University of Denver

TREATMENT OF MINE DRAINAGE WATERS has fast become a necessity for all mining operations, and regulations governing discharge into local waterways can be expected to become even more stringent. One aspect of mine water treatment—removal of dissolved metals—can be accomplished by a two-stage process developed at the Denver Research Institute (DRI). The first stage of the process treats the waters by lime neutralization to eliminate Fe and Al. A second stage then removes Cu, Zn, Mn, and heavy toxic metals (Hg, Cd, As) by adding sulphide to the waters.

The quantitative effect of both stages of treatment can be predicted by a mathematical description based on the equilibrium relations involved:

$$mM^{+d} + dD^{-m} \rightarrow M_mD_d \downarrow \qquad (1)$$

where M is the metallic cation of charge $(+d)$ and D is the anion of charge $(-m)$.

The removal of dissolved metals by neutralization (stage 1) is predicted quantitatively. Total sulphide addition to achieve removal of specific metals is predicted for stage 2.

Table 1 provides the set of numerical constants used to describe the system mathematically. These values were selected from the literature as yielding the best approximation to measured results. Butler[1] has pointed out that K_{sp} values are often so small that they are outside the realm of realistic measurement. Therefore, a set of values that gives consistent results is all that is needed.

DRI process successful in field studies

Field investigation for the DRI process included erection of a treatment pond beside Mineral Creek in the

Fig. 2—Results of sulphide addition to Idaho drainage sample

Fig. 3—Results of sulphide addition to Montana drainage sample

Fig. 4—Measured vs. computed values for neutralization of mine drainage
(Mineral Creek, Colo.)

Fig. 5—Theoretical vs. measured results for neutralization of mine drainage
(Mineral Creek, Colo.)

Table 1—Solubility-product constants for hydroxides and sulphides of heavy metals in mine drainage

	Hydroxide	Sulphide
Ferric iron	1.1×10^{-36}	2.0×10^{-88}
Aluminum	1.2×10^{-32}	—
Cupric copper	6.0×10^{-20}	7.7×10^{-36}
Zinc	7.1×10^{-18}	1.6×10^{-24}
Manganese	1.6×10^{-13}	2.5×10^{-13}

Rocky Mountains, west of Denver, Colo. Fig. 1 shows the design of the pond. A single pond can be used to separate the minerals of potential economic value (e.g., Cu and Zn) from Fe and Al, because $Fe(OH)_3$ and $Al(OH)_3$ will not settle when a pond is even slightly agitated by surface breeze. The sulphides, on the other hand, precipitate almost immediately after being introduced into the settling pond.

Control of pH in the two stages of the process was quite simple, requiring only good mixing for 3 to 5 min in the

contact chambers (1 and 2 in Fig. 1). Neutralization of the influent from pH 2.6 to pH 5.0 was achieved in the first stage, and sulphide addition in the second stage brought the pH to 6.5—the ambient regional pH.

Fig. 2 is an experimental plot of the behavior of metals in a drainage water sample from an Idaho mine tunnel after treatment by the DRI process. Mn was completely removed, although previously reported dual processes had removed Mn only partially.[2] The DRI process also succeeded in completely removing the toxic metals As, Cd, and Hg.

Fig. 3 shows the pattern of metal removal from a sample of drainage water taken in Montana. All Cu was apparently removed by neutralization before pH 3 was achieved.

Simulation of two-stage DRI process

Equation 1 is the basis for mathematical simulation. For example, the precipitation of ferric iron occurs as

$$Fe^{+3} + 3OH^- \rightarrow Fe(OH)_3 \downarrow$$

and the terms in equation 1 now become: $d = 3$, $m = 1$, $M = Fe^{3+}$, and $D = OH^-$.

The dissociation of water must also be considered:

$$H^+ + OH^- \rightarrow HOH$$

Finally, when the anion is sulphide ion, two additional equilibria must be expressed.

$$H^+ + S^{=} \rightarrow HS^-$$
$$H^+ + HS^- \rightarrow H_2S$$

With the values reported in Table 1, equilibrium for the five metals of interest can be computed as a function of their concentration, the solution pH, and the amount of sulphide added. The two-stage DRI process was simulated by assuming a starting mixture consisting of typical Mineral Creek water, then raising the pH to 5.0, after which a given amount of sulphide was added.

Fig. 4—a set of curves for neutralization alone—illustrates the most difficult case to compute, because the liquid volume is changing. The plot in Fig. 4 suggests the presence of an unreported metal. The lag of pH rise and the delay in Zn precipitation indicate that another cation may be consuming OH^- ion. The unreported metal could be Mo, common in the Rocky Mountains but never reported in state or Federal routine sampling. Alternately, the metal could be As, which has been found in waters of this region in concentrations up to 20 ppm.

Computation is simpler when the sample of mine drainage water doesn't undergo a volume change. This is the case when solid chemicals, such as lime and sulphide, are added. Fig. 5 shows the results of such a computation for neutralization, and Fig. 6 shows the results of sulphide addition alone. The neutralization plot (Fig. 5) is fairly satisfactory at all points, but the plot for sulphide addition (Fig. 6) appears useful mainly as a predictive tool for Cu and Zn precipitation. □

Project Summary

Characterization of Boliden's Sulfide-Lime Precipitation System

M. Blythe, K. Schwitzgebel, J. C. Terry, Christina Sund-Hagelberg, and D. Bhattacharyya

The Project Report summarized here provides information on the soluble sulfide precipitation process (Na_2S) used at a copper/lead smelter for treatment of wastewater. The study presents the results of a sampling study which aimed to define the process kinetics of a full scale plant. The generation of H_2S gas, metals removal, and sludge handling are discussed.

Excellent removal of most metals, including arsenic was shown. Process control problems prevented 99%+ removal of all metals, however.

This Project Summary was developed by EPA's Industrial Environmental Research Laboratory, Cincinnati, OH, to announce key findings of the research project that is fully documented in a separate report of the same title (see Project Report ordering information at back).

Introduction

Sulfide precipitation is an effective process for the treatment of industrial wastes containing highly toxic heavy metals. The attractive features of the sulfide precipitation process are: attainment of high degree of metal removals over a broad pH range, effective precipitation of certain metals (such as: As, Cu, Cd, Hg) even at very low pH, low detention time requirement in the reaction tank because of the high reactivity of sulfides, and the feasibility of selective metal recovery. With sulfide precipitation, the high reactivity of sulfides (S^{2-}, HS^-, H_2S) with heavy metal ions and the very low solubilities of the heavy metal sulfides over a broad pH range are features not found with the hydroxide precipitation processes.

Industries engaged in metal finishing or metal production operations use large quantities of contact process water, and the spent process wastewater streams contain moderate to high concentrations of As, Cd, Cu, Zn, Pb, Hg, etc. Various physico-chemical treatment methods to remove heavy metals have been reported in the literature. Hydroxide (lime) precipitation of heavy metals followed by settling of the precipitates is most often used to treat industrial wastewaters. However, the minimum solubilities for different metals occur at different pH values and the hydroxide precipitates are amphoteric in nature and thus maximum removal efficiency of mixed metals cannot be achieved at a single precipitation pH. Hydroxide precipitation of arsenic cannot be achieved at any pH value. Arsenic precipitation occurs only at very high pH when lime is used to form calcium arsenate.

Sulfide precipitation (with Na_2S or NaHS) is an effective alternate technology. Sulfide precipitation processes to remove heavy metals have gained considerable importance[1-4]. The overall objective of this investigation is to establish the effectiveness of the sulfide

*Table 3. Residual Metal Concentrations Obtained with Na_2S Precipitation of Actual Wastes**

pH = 8.0
Sulfide dosage = 0.5 X

Waste	Sulfide Dosage	As	Se	Cd	Zn	Cu	Fe
				Concentration, mg/l			
Batch I	5mM (162 mg/l S)	1.0-2.0	0.5-1.0	0.06-0.2	1.0-1.4	0.1-0.2	0.5-0.8
Batch II	14mM (448 mg/l S)	1.0-2.5	1.0-3.0	0.05-0.08	0.8-1.1	0.2-0.5	0.4-0.5

Figure 3. Effect of molar feed ratio of Fe/As on arsenic removal by a combination hydroxide - sulfide precipitation.

reagent by dissolved SO_2 (sulfite) present (Table 4) in the wastewater. The control technique of sulfide dosage by pH rise was found to be insufficient for simultaneous arsenic and zinc removal at optimal efficiency. In order to understand the importance of sulfite-sulfide side reaction at acidic pH values, bench-scale studies were conducted with single metal salts in the presence of sulfite at acidic pH values. Depending on the metals studied, part of the Na_2S was consumed by SO_3^{2-} to form elemental sulfur and thiosulfate. Even with sulfide overdoses at low pH values no H_2S gas loss from the solutions occurred (also observed in full-scale tests) due to SO_3^{2-} - H_2S reactions. At stoichiometric Na_2S dosages (to form AS_2S_3, ZnS, etc.) the sulfite-sulfide reaction played an important role only during precipitation of As and Zn at low pH values. The decrease in separation for As and Zn in the presence of sulfite is shown in Figure 5. For ZnS formation (because of low solubility product) the sharp increase in residual Zn concentration (as shown by cross-hatched area) and consumption of SO_3 (as shown by a decrease in SO_3 concentration) are evident from Figure 5. The effects of sulfide-sulfite reaction were found to be negligible above pH 5.

In summary, the feasibility of a combination of hydroxide-sulfide precipitation (at pH 8-9) process, and a process involving sulfide precipitation (at pH 3-5) followed by lime precipitation, is established to achieve a high degree of separation of heavy metals and arsenic. The combination hydroxide-sulfide process required only 60% of the theoretical Na_2S dosage to provide effective separations of heavy metals and arsenic. Simple sulfide precipitation at pH 3-4 also provided excellent removals for Cu, Cd, Hg, and Pb. For precipitation of arsenic and zinc sulfide at pH < 5, the side reaction between sulfite (if present in wastewater) and sulfide must be considered. Hydrogen sulfide gas formation was never found to be a problem during precipitation because of the high reactivity of sulfides and heavy metals.

This project was supported by a research grant (R804568) from the U.S. Environmental Protection Agency to the University of Kentucky.

Permutit Package Precipitator

The Permutit Precipitator offers a highly efficient means for removing impurities from a liquid by precipitation, adsorption, settling and upflow filtration. This unit has found wide application among municipalities and industries for water and waste water clarification. It is universally accepted for coagulation and clarification and for the removal of suspended matter, color, iron, manganese, silica, and heavy metals, in addition to softening and dealkalization.

Precipitator Applications

Turbidity Removal
The Precipitator's sludge blanket is particularly efficient in removing small particles that are difficult to remove by other filtration processes. The proper mixing of chemicals causes the formation of a large, tough floc throughout the sludge blanket. This assures the maximum adsorptive and straining effect in removing turbidity. Final polishing of the water may then be accomplished with filters.

Color Removal
Color is removed from water by the use of coagulants applied in the most favorable pH range. In addition, certain waters may require clay, chlorine, polyectrolytes, or activated carbon. The Precipitator is particularly applicable for color removal due to the intimate contact between the water and the adsorbents in the mixing and sludge blanket zones.

Alkalinity Reduction
The Precipitator may be operated to reduce calcium bicarbonate alkalinity alone or to reduce both calcium and magnesium alkalinity. Its efficient use of chemicals is most effective for this application.

Silica Removal
One of the methods for the removal of silica from water has been the use of metallic hydroxide sludges as silica adsorbents. In Precipitator installations the efficient use of the adsorbent powers of the sludge has proved to be of great value for silica removal.

Taste and Odor Removal
The Precipitator is widely used for the removal of tastes and odors from water supplies. Activated carbon is fed into raw water, entering the the Precipitator at the same time that coagulant chemicals are introduced. The adsorbent properties of the activated carbon are utilized to the fullest extent during the prolonged and intimate contact with agitated and suspended sludge provided by the Precipitator.

Heavy Metals Removal
The dense sludge blanket of the Precipitator is especially effective when precipitating metals as sulfides or hydroxides. This property offers a critical advantage where permissable discharges of metal residuals are limited to fractions of a part per million.

Precipitator Advantages

Superior Performance
Low turbidity Precipitator effluent is virtually always superior to the effluent of conventional clarifier-softeners.

Excellent Chemical Efficiency
Action of suspended sludge in the mixing zone and upflow through the sludge blanket achieves highly efficient chemical utilization.

Positive Agitation
Large, slow moving agitator blades completely mix water, chemicals and sludge.

Effective Sludge Blanket
Sludge blanket particles are effectively distributed from top to bottom for optimum contact and filtration.

Easy Installation
Precipitator tanks are shipped set up with agitator and reducer assembled and installed.

Adaptable To Tube Settlers
Permutit Chevron shaped tube settlers can easily be installed to increase flow rate up to 40 percent over standard capacity. Tube settlers support grids are built into all Precipitators.

Adapts To Variable Flow Rates
As the rate of flow changes, the height of the sludge blanket adjusts to a level which provides the proper area for the new rate.

Lengthened Filter Runs
The low turbidity effluent of a Precipitator places very little load on downstream filters. This permits longer filter runs than previously possible and lowers treatment costs.

**Detention time 60 minutes.

Package Precipitator/Solids Contact/Clarifier

Suggested Specifications

Scope
The intent of these specifications is to provide complete factory fabricated Precipitator type clarification equipment to treat _____ gpm total flow. The detention time at design capacity shall be one hour (40 minutes minimum with optional tube settlers). The equipment to be installed shall be ____ wide × ____ long × 10'-6" high.

General
Furnish _____ Permutit standard model _____ automatic horizontal Precipitator unit(s).

Tank
The Precipitator outer tank shall be fabricated of ¼" steel plate complete with bottom. The tank shall include inlet and effluent distributing flumes constructed of ¼" steel plate along the entire inside length for proper distribution and collection of the water. The mixing compartment is to be separated from the sludge filter compartment by a ¼" steel water tight sloping baffle. Inlet, outlet, overflow and drain connections shall be provided on the tank.

Internals
A complete paddle type agitator mechanism shall be furnished consisting of shaftings, paddles, water lubricated bearings and guides, designed so as to assure complete agitation of the mixing zone and avoid settling of material on the bottom of the Precipitator. The agitator drive shall consist of ____ HP, T.E. motor with speed reducer, required sheaves and belts for speed adjustment in a 4:1 range.

The unit shall inlude provision for the collecting, concentrating, and blowoff of sludge and back flushing of sludge lines. The sludge concentrator shall run the length of the unit at the bottom of the sludge filter compartment. A perforated PVC sludge blowoff header shall be installed in the concentrator. A PVC port header shall also be provided to move material too heavy to be carried into the sludge concentration zone. Timers, solenoid valves, and diaphragm valves for controlling the automatic desludging of the Precipitator and the automatic back flushing of the concentrator headers shall be provided.

Sampling
Five ½" sample lines and sample points shall be provided. The points of sampling shall be: in the upper portion of the mixing zone, in the sludge concentration zone, in the lower sludge blanket zone, in the upper sludge blanket zone, and in the effluent water zone. The sample lines shall terminate in a sample sink attached to the Precipitator tank.

Finish
The steel tank and internal parts are to be commercially sandblasted, primed with one (1) shop coat of Inertol No. 621, or equal, and shipped set-up with all internal components including agitator, sludge and port piping installed.

Operation
The unit shall provide a highly efficient means for removing impurities from a liquid based on the upflow sludge blanket principle. It shall include an inlet flume, a mixing compartment, and upflow sludge filter compartment, a sludge concentration zone and an effluent flume.

Chemically dosed water introduced into the inlet flume shall be uniformly distributed to the mixing compartment over the entire length of the unit. The agitators in the mixing compartment shall assure intimate contact between water and chemicals, and keep the sludge blanket in proper suspension. The sloping baffle separating the mixing compartment from the sludge filter compartment shall serve not only to keep the mechanical agitators from disturbing the sludge blanket, but also to provide a gradually increasing upflow area to enhance settling. The resulting sludge blanket provides for entrapment and holding of fine particles. Units not providing baffles which separate the mixing and sludge filter zones will not be acceptable.

The maximum area of the upflow Precipitator section (the greatest available clear water disengaging area) shall provide for an upward velocity not exceeding 1.25 gpm per sq. ft. when operating at design capacity. (For optional operation with tube settlers the upward velocity shall not exceed 2.4 gpm per sq. ft. of tube settler area, and tube settlers shall occupy an area not less than 70 percent of the maximum Precipitator section).

Work By Others
Receive, unload, and set equipment on concrete foundation pad. Provide and install all external piping and electrical work. Finish paint.

Options
- Inlet Flow Meter
- Meter Initiated Blow-Off Cycle
- Inlet Control Float Valve
- Tube Settlers
- Chemical Feed Equipment
- Pump Suction Tanks
- High Low Float Switches
- Transfer Pumps
- Chemical Feed Timers
- Manual Starter for Agitator Drive Motor

CONCLUSIONS

OVERVIEW

Three sulfide precipitation processes that use soluble sulfides have been demonstrated (in a continuously operated bench-scale plant) as practical waste treatment processes for removing heavy metals from wastewater. The levels to which heavy metals can be reduced, and the costs of treatment compared to conventional lime treatment, are developed in this report.

The lime, sulfide polished and filtered (LSPF) process is the optimum sulfide process. For many wastewaters, treatment by the lime process followed by filtration is almost as effective as the LSPF process and costs far less.

EFFECTIVENESS OF PROCESSES FOR REMOVING HEAVY METALS

Based only on the reduction in concentration of five heavy metals (cadmium, chromium, copper, nickel, and zinc) in the effluents analyzed and without considering cost:

- The lime only, clarified (LO-CL) process is the least effective.
- Processes lime only, clarified and filtered (LO-CLF) and lime with sulfide, clarified (LWS-CL) are equally effective and better than the LO-CL process.
- Processes LSPF and lime with sulfide, clarified and filtered (LWS-CLF) are equally effective and better than any of the other three.

OPERATING AND CAPITAL EQUIPMENT COSTS

Each of the improvements to the basic LO-CL process carries a cost penalty. Tables 1 and 2 show that:

- The addition of a filtration operation (conversion to the LO-CLF process) adds from 0.4 to 0.7 percent to the operating costs and from 0.8 to 1.7 percent to the capital costs.
- The addition of a sulfide polishing operation, which includes filtration (conversion to the LSPF process), adds from 4.8 to 8.6 percent to the operating costs and from 8.6 to 11.6 percent to the capital costs.
- Conversion to a lime-with-sulfide process increases the capital cost by 6.2 to 11.6 percent; for a small plant, the process increases the operating cost by 7.1 to 7.8 percent, and for a medium or large plant, the process increases the operating cost by 26.4 to 39.5 percent.

TABLE 1. COMPARISON OF OPERATING COSTS

Operating cost of: / Plant capacity	Conventional lime plant with no filtration	Lime plant with filtration added (%)	Lime plant with sulfide "polish" operation, including filtration (%)	Lime-with-sulfide plant with no filtration (%)	Lime-with-sulfide plant with filtration added (%)
	LO-CL	LO-CLF	LSPF	LWS-CL	LWS-CLF
37.85 m^3/day (10,000 gal/day)	\$5.96/m^3 (\$22.6/1,000 gal)	+0.7	+4.8	+7.1	+7.8
757 m^3/day (200,000 gal/day)	\$0.90/m^3 (\$3.39/1,000 gal)	+0.4	+8.0	+26.4	+26.8
1,893 m^3/day (500,000 gal/day)	\$0.55/m^3 (\$2.08/1,000 gal)	+0.5	+8.6	+39.0	+39.5

TABLE 2. COMPARISON OF CAPITAL COSTS

Capital cost of: / Plant capacity	Conventional lime plant with no filtration	Lime plant with filtration added (%)	Lime plant with sulfide "polish" operation, including filtration (%)	Lime-with-sulfide plant with no filtration (%)	Lime-with-sulfide plant with filtration added (%)
	LO-CL	LO-CLF	LSPF	LWS-CL	LWS-CLF
37.85 m^3/day (10,000 gal/day)	\$233,000	+1.7	+11.6	+9.4	+11.6
757 m^3/day (200,000 gal/day)	\$799,000	+0.8	+11.6	+9.1	+10.0
1,893 m^3/day (500,000 gal/day)	\$1,296,000	+1.1	+8.6	+6.2	+7.2

SLUDGE DISPOSAL COSTS

The costs developed here include estimates for sludge disposal, which are based on the assumption that a sulfide sludge will not carry any significant cost penalty. At this stage, we do not know the additional surcharge, if any, that might be added to the disposal charges for a sulfide sludge.

EFFECTIVENESS OF SPECIFIC PROCESSES FOR REMOVING HEAVY METALS

The same order of preference as that given on page 2, with more details about individual metals, can be seen in Tables 3 and 4, which show the mean levels of the five metals before and after treatment.

The tables show that cadmium, copper, and zinc follow the same hierarchy as we established on page 2; that is, LO-CL is least effective, LO-CLF and LWS-CL are more

effective, and LSPF and LWS-CLF are most effective. The logarithmic mean removal of these three metals is 96.3 percent or greater for the two most effective processes, with a logarithmic mean effluent concentration of less than 50 μg/L.

Nickel removal does not follow the established hierarchy completely; when the logarithmic means are considered, the five processes are roughly equivalent. When the arithmetic means are considered, the hierarchy is the same as that established for cadmium, copper, and zinc. The logarithmic mean nickel removal is 88.4 percent or

TABLE 3. ARITHMETIC MEAN INFLUENT AND EFFLUENT CONCENTRATIONS FOR THE FIVE PROCESSES

Concentrations in μg/L (values in parentheses are percentage reductions from raw feed)

Heavy metal	Raw feed	LO-CL	LO-CLF	LWS-CL	LSPF	LWS-CLF
Cadmium	4,805	144 (97.00)	103 (97.86)	25 (99.48)	13 (99.37)	8 (99.83)
Copper	4,136	963 (76.72)	673 (83.73)	521 (87.40)	96 (97.68)	70 (98.31)
Chromium	26,006	603 (97.68)	58 (99.78)	370 (98.58)	58 (99.78)	86 (99.67)
Nickel	18,617	2,021 (89.14)	1,561 (91.62)	1,506 (91.91)	652 (96.50)	751 (95.97)
Zinc	259,865	8,385 (96.77)	6,629 (97.45)	491 (99.81)	517 (99.80)	422 (99.84)

TABLE 4. LOGARITHMIC MEAN INFLUENT AND EFFLUENT CONCENTRATIONS FOR THE FIVE PROCESSES*

Concentrations in μg/L (values in parentheses are percentage reductions from raw feed)

Heavy metal	Raw feed	LO-CL	LO-CLF	LWS-CL	LSPF	LWS-CLF
Cadmium	135	31 (77.04)	18 (86.67)	8 (94.07)	5 (96.30)	4 (97.04)
Copper	673	109 (83.80)	63 (90.64)	49 (92.72)	21 (96.88)	16 (97.62)
Chromium	1,039	136 (86.91)	24 (97.69)	108 (89.61)	24 (97.69)	32 (96.92)
Nickel	976	156 (84.02)	118 (87.91)	155 (84.12)	93 (90.47)	113 (88.42)
Zinc	23,904	820 (96.57)	210 (99.12)	195 (99.18)	46 (99.81)	31 (99.87)

* Log average of x_1 through $x_n = \log^{-1}\left(\frac{\sum_1^n \log x}{n}\right)$

greater for the two most effective processes, and the logarithmic mean nickel level in the effluents is 113 μg/L or less.

Chromium removal is not significantly improved by the presence of sulfides. That is, the unfiltered effluents (LO-CL and LWS-CL processes) showed logarithmic mean concentrations that were about equal at 136 and 108 μg/L, and the logarithmic means for the filtered effluents (LO-CLF, LSPF, and LWS-CLF) were also about equal at 24, 24, and 32 μg/L, respectively. This grouping clearly indicates that filtration after clarification had exerted a marked effect. Logarithmic mean chromium removal rates are 86.9 percent or greater for the unfiltered effluents and 96.9 percent or greater for the filtered. Logarithmic mean chromium levels of 32 μg/L or less were obtained in the effluents from the filtered processes and 136 μg/L or less in the unfiltered.

These findings agree with the observation that chromium, unlike the other metals considered, precipitates a hydroxide, not a sulfide, in the presence of sulfide ions. Thus, no difference would be anticipated between the removal rates of hydroxides precipitated by lime and hydroxides precipitated by sulfides. The solubility constant of the hydroxide would govern in both cases.

Lead was removed effectively in some tests, such as Runs 5, 8, 14, and 15. In each of these, the removal efficiency is 96.6 percent or greater for all five processes. However, in many other runs, the efficiency of removal is poor, ranging from 0 to 77 percent. In two cases, Runs 1 and 4, a striking improvement was noted in the effluents from filtered processes compared with the effluents from unfiltered processes. In Run 1, the removal efficiency of the filtered process is 91.1 percent or greater, but virtually no removal took place in the unfiltered process. In Run 4, the filtered-process removal efficiency is 82 percent or greater, but the efficiency is only 30 to 64 percent for the unfiltered process. Further work is needed to determine the underlying causes of these variations in the effectiveness of the processes. Based on the present tests, for lead removal, the sulfide processes apparently have no advantage over the lime process.

When the sulfide processes are used, silver removal is not significantly different from conventional lime processing.

Tin is removed efficiently by all processes in Runs 3, 7, and 12, with greater than 95-percent removal efficiency. Runs 4 and 5 are less efficient, with removal ranging from 19 to 86 percent. The sulfide processes are no more efficient than the conventional lime processes.

CONTROL OF SULFIDE CONCENTRATION BY SPECIFIC ION ELECTRODE

The dependability of the sulfide specific ion electrodes that were used to control sulfide levels was excellent during the 6-month period while the bench-scale plant was in operation. Ruggedness, freedom from drift, and ease of electrode maintenance were roughly intermediate when compared to those of a typical combination pH electrode and to those of an oxidation-reduction-potential (ORP) probe.

Project Summary

Treatment of Metal Finishing Wastes by Use of Ferrous Sulfide

M. B. Yeliger, G. Bagenski, and R. M. Schlauch

M. B. Yeliger, G. Bagenski, and R. M. Schlauch are with the Permutit Company, Inc., Monmouth Junction, NJ 08852.
Mary K. Stinson is the EPA Project Officer.

The complete report, entitled "Treatment of Metal Finishing Wastes by Use of Ferrous Sulfide," (Order No. PB 81-233 579; Cost: $9.50, subject to change) will be available only from:
National Technical Information Service
5285 Port Royal Road
Springfield, VA 22161

The demonstration of a now patented sulfide precipitation process ("Sulfex" ™), which removes heavy metals from metal finishing wastewaters, was performed to verify its operational practicability and performance quality. Operational data was also gathered for an economic evaluation of this process.

The study was performed at a carburetor manufacturing plant in Paris, Tennessee. Here, "Udylite" processes are used for chromate conversion coatings on aluminum and zinc carburetor castings before assembly.

A newly installed sulfide precipitation system removes chromium and zinc from the plant's combined metal finishing process wastewater. It also removes suspended material such as precipitated aluminum, iron, and phosphates. Major steps in the system are: equalization and neutralization of untreated wastewater, precipitation of metals and sedimentation of suspended solids, polishing of settler effluent with dual media filtration, and final dewatering of settled sludge.

Results show all metals and suspended solids were removed to levels well below both the City of Paris sewer system limitations and the State of Tennessee guidelines for indirect discharges to sewer systems. A dewatered sludge was produced as a firm, dry cake in a filter press without the use of conditioning agents. No hydrogen sulfide odor was detected from the reaction process treated effluent, or the solid waste produced. Jar tests were demonstrated to be a valuable tool for maintaining good process control and economical operation.

The chemical cost of sulfide precipitation has been found to be directly dependent upon the concentrations of combined zinc and hexavalent chromium present during the sulfide reaction process. Sulfide precipitation was shown to be an economical as well as effective treatment process for this type of wastewater.

This report was submitted in fulfillment of Grant No. S-804848 by Holley Carburetor Division of Colt Industries under the sponsorship of the U.S. Environmental Protection Agency. This report covers the period July 11, 1978 to August 11, 1978, and work was completed as of August 25, 1978.

This Project Summary was developed by EPA's Industrial Environmental Research Laboratory, Cincinnati, OH, to announce key findings of the research project that is fully documented in a separate report of the same title (see Project Report ordering information at back).

Introduction

In April 1974, a laboratory and pilot-plant study of a new wastewater treatment process, using sulfide precipitation, was sponsored by the Metal Finisher's Foundation under Grant No.

R802924-01 from the Environmental Protection Agency. In July 1978, another study was undertaken to demonstrate effectiveness, operability, and cost of this new process called "Sulfex"™ as a full-scale installation at Holley Carburetor Company in Paris, Tennessee.*

Laboratory and Pilot-Plant Study

This work is described in the report "Treatment of Metal Finishing Wastes by Sulfide Precipitation" EPA-600/2-77-049, February 1977.* The project involved precipitating heavy metals normally present in metal finishing wastewaters by a novel process which employs ferrous sulfide addition as well as by conventional treatment using calcium hydroxide for comparison purposes. A simulated metal finishing wastewater containing common heavy metals and chelating agents was used in this laboratory and pilot-plant study. Sulfide precipitation was demonstrated to be a technically viable process that is superior to conventional hydroxide precipitation for removal of copper, cadmium, nickel, chromium, and zinc from the given influent.

Full-Scale Study

The present study was made during the startup of a 7.9 m^3/hr (35 gpm) wastewater treatment system at a carburetor manufacturing plant. Here, the production of carburetors produces wastewater from chromate conversion coating of zinc and aluminum castings by a "Udylite" process. Combined wastewaters from these metal finishing operations contain heavy metal pollutant concentrations in excess of local and state limits set for direct discharge to the city sewer system. Therefore, a safe, reliable, and economic wastewater treatment process was needed by the manufacturer to meet the imposed discharge requirements.

The metal finishing operations used at the plant involved degreasing, deburring, deoxidizing, acid etching, and chromate bath treatment to give carburetor castings corrosion resistant coatings. In the process, various materials including zinc, hexavalent chromium, aluminum, ortho- and polyphosphates, silicates, organic surfactants and chelants, as well as chelated metals, are released into the plant's wastewater discharge.

Since manufacturing specifications vary, all castings do not undergo treatment by each of these finishing operations. Furthermore, the production schedule is quite variable. As a result, the composition of the wastewater fluctuates periodically on hourly, daily and weekly bases.

This type of metal finishing operation is generally used for providing corrosion resistant coatings on surfaces of a wide variety of metal parts, components and appliances. Consequently, these wastewater characteristics are typical of many industrial manufacturing discharges that have to be treated to meet present and future discharge standards.

The laboratory and pilot-plant study had demonstrated the effectiveness of sulfide precipitation on a synthetically prepared metal finishing wastewater. The full-scale system study at the plant is useful in further proving that the process is practical under actual manufacturing conditions. For example, Table 1 summarizes the overall effectiveness of the process in removal of pollutants. Figure 1 shows the total chemical operating cost, on a per shift basis. Other variables and economics are described individually on per shift and per year basis. Therefore, this study shows how practical, controllable, and economical it is to operate the process under the fluctuating contaminant loadings that are characteristic of many metal finishing wastewaters.

Conclusions

Effectiveness

The effectiveness of the sulfide precipitation process has demonstrated that heavy metals can be removed from metal finishing wastewaters to very low levels. The effluent quality produced by this wastewater treatment process (as monitored by direct flame atomic absorption and diphenyl carbazide colorimetric methods for metal analyses) reveals that the process achieves metal values close to or less than are *routinely* detected by the accepted analytical methods (i.e. Cr and Fe detected at 0.05 mg/l, Cu and Zn detected at 0.01 mg/l).

Economics

The chemical cost of the sulfide precipitation process is directly dependent upon the influent metal loading of various heavy metals. At the carburetor plant, influent zinc and hexavalent chromium are the metal concentrations that dictate the dosage of ferrous sulfide that is required. Here, the chemical cost of sulfide precipitation is competitive with the cost of conventional bisulfite and hydroxide treatment for removal of average concentrations of zinc and hexavalent chromium in the untreated wastewater (i.e. about 34 mg/l Zn and 34 mg/l Cr^{+6}).

When hexavalent chromium is present in combination with other heavy metals, as it is at this plant, there can be a savings in equipment cost with sulfide precipitation since the metals can be removed simultaneously in one step. But, as the concentration of zinc (or other heavy metals increases) the chemical cost of direct treatment by sulfide precipitation becomes increas

Table 1. Average Wastewater Compositions During "Sulfex"™ Study

Metal	Untreated* influent	Treated* effluent	Most stringent state or city limit for Paris, Tenn. STP
	(mg/l)	(mg/l)	(mg/l)
Zn	39.5	<0.07†	0.04
Fe	0.52	0.10	—
Cu	<0.01	<0.01	0.5
Cr	32.3	<0.04	1.0
Cr^{+6}	35.6	<0.01	0.05
TSS	46.5	<1.0	<1600

*Average of 22-day test monitoring period (7/11 to 8/11/78).
†This value is the calculated maximum average for all effluent zinc analysis during this period. As illustrated, elimination of the atypical first sample value (1.5 mg/l Zn) gives an average effluent zinc of less than 0.03 mg/l.

*Schlauch, R.M. and A.C. Epstein. "Treatment of Metal Finishing Wastes by Sulfide Precipitation," EPA-600/2-77-049, Environmental Protection Technology Series, Industrial Environmental Research Laboratory, Cincinnati, Ohio, Feb 1977, pp. 1-74.

Figure 1. Total chemical cost as a function of time

ingly more than by hydroxide precipitation. At Holley, the chemical cost for sulfide precipitation treatment is justified since conventional treatment cannot effectively meet the city sewer limitations (i.e. 0.1 mg/l zinc maximum).

In all cases, however, the relative economics can be evaluated beforehand by the average heavy metal concentrations present in the wastewater. In some cases, it may be more economical to remove the bulk of the heavy metals by hydroxide precipitation, and apply sulfide precipitation as a polishing step when stringent criteria must be met.

Most of the basic equipment used for the sulfide precipitation process is the same as would be required for a conventional wastewater treatment process. Therefore, major capital costs as well as operating costs are estimated to be commensurate for both of these treatment processes.

Operation

The operation of the wastewater treatment system at the carburetor plant is basically simple. Good control is maintained because the system is designed to handle sudden changes in wastewater flow and composition.

An equalization tank is an essential part of the system for dampening fluctuations in wastewater flow and metal concentrations into the reactor-settler unit. The concentrated waste sump receives spent metal finishing baths and slowly feeds them into the equalization tank. This sump is essential to minimize variations that could complicate the operation and downgrade the effectiveness of the waste treatment process.

Since it is possible that some residual suspended solids carryover can occur periodically from the settler, the dual-media filter is necessary to ensure removal of suspended metals from the effluent before discharge to the city sewer system.

Without further use of coagulants or conditioners, a filter press will provide excellent dewatering of the settler sludge. A dry sludge cake is produced that releases easily from the press and is ready for disposal.

Control

The pH control of the neutralization process is accomplished in the equalization tank. This type of system is satisfactory for maintaining an appropriate pH for effective metal precipitation in the reactor-settler unit. High concentrations of hexavalent chromium in the wastewater can cause moderate pH increases in the reactor-settler effluent. Controlling the pH at 8.0 in the neutralization step is an effective way of compensating for this pH increase.

Periodic visual jar tests performed on the reactor-settler influent are a satisfactory means of monitoring and controlling optimal ferrous sulfide and polyelectrolyte dosages. These visual tests, for determining chemical dosage requirements, eliminate the need for laboratory analysis of influent heavy metals.

Operating Personnel

The need for wastewater treatment system operators must be determined on the basis of each plant. Due to frequent variation in the mode of the metal finishing operations at the demonstration plant, a full-time operator is required on each shift to monitor the wastewater treatment system. However, in installations where manufacturing processes are not as variable on a daily and weekly basis, a full-time operator may not be required on each shift.

Recommendations

The sulfide precipitation process has demonstrated that more complete metal removal can be obtained and acceptable effluent quality achieved, as opposed to conventional hydroxide treatment of metal finishing wastewaters. But the cost of precipitating most heavy metals (except hexavalent chromium) is higher by sulfide methods than by the hydroxide methods on a per unit weight of metal removed basis.

Present day technology reveals that *hydroxide precipitation* removes high percentages of zinc and other metals from metal finishing wastewaters. However, this removal method can still allow unacceptably high residuals of heavy metals in the treated effluent for discharge.

Therefore, in cases of very high metal loadings, a combination of the two methods in series should prove to be an economically attractive way of achieving superior quality effluents. Sulfide precipitation, is thus precipitation, as a polishing step following conventional hydroxide recommended when either heavy metal loadings on new systems are high enough to warrant the additional equipment or a conventional treatment system already exists.

SULFEX™ Heavy Metals Waste Treatment Process

Sulfex is a proprietary system developed by Permutit for removing heavy metals from process waste streams. Sulfex has particular application for the treatment of metal finishing and plating waste waters and for removing chromates and similar metallic constituents from cooling tower blowdown effluent. A practical and economic waste treatment process, Sulfex sets a new criteria for effective control of heavy metal pollution.

Questions and answers about the Sulfex treatment process . . .

1. Why are the regulatory agencies concerned over the discharge of so called "heavy metals"?

Because heavy metals, which include zinc, copper, cadmium, nickel, chromium, mercury, lead, etc., have been found to have a delayed but very serious impact on the natural food chain going from algae through lower aquatic life to higher animals and humans. The natural concentration of such metals in surface water is exceedingly small, but concentrations are increased along the food chain until toxic levels can destroy certain species. For instance, populations of shell fish have been eliminated in some areas, and there have been cases of brain damage, birth defects and death to human beings attributed to "biomagnification" of some heavy metals.

When heavy metals are discharged into municipal sewage treatment plants, there is some danger of direct toxicity to essential bacteria. Normally, the heavy metals concentrate in the sludge produced. This sludge can be toxic to some plants if applied to land, or toxic to marine life if dumped at sea.

Much more is to be learned about the delayed effects of heavy metal discharge. It is evident, however, that the discharges should be minimized.

2. What industries or operations typically discharge these metals?

The plant waste streams of metal plating and finishing operations, certain textile, dye and pigment operations, mercury cell operations, metal fabricators, smelting and ore handling operations and cooling tower blowdown usually contain one or more of these toxic metals.

3. What do the regulations call for?

Federal regulations require the "best practical technology" to be applied by 1977, and "the best available technology" to be applied by 1983. The discharge permit system, as administered in different geographical locations, may set more specific requirements, and any local regulatory agency can set more stringent demands but not less stringent demands than the federal government.

Discharges going into a municipal treatment system may have different limitations than discharges into surface water.

It is wise to determine the local regulations before action is taken.

4. What has previously been considered the "best practical technology" for treating waste containing heavy metals?

In many cases, mixtures of these heavy metals have been treated by pH adjustment with either lime or caustic soda to cause precipitation of metal hydroxide sludge. This is sometimes called "Lime and Settle" process or the hydroxide process.

Chromium presents a special problem when it is present as a chromate, or in its hexavalent state. It first must be reduced to the trivalent state before it can be precipitated as a hydroxide. The reduction step commonly is carried out at a pH of about 2 with a reducing agent such as sulfur dioxide gas, sodium metabisulfite, or ferrous sulfate. When the reduction is complete, the pH must be raised to allow the chrome hydroxide to form. Therefore, hexavalent chrome wastes are normally isolated from other wastes and treated separately.

5. Are there any problems or inadequacies with the hydroxide process?

Yes, the hydroxide process is often not capable of removing enough of the heavy metal contaminants to achieve specified discharge levels. There are a number of reasons for this.

(a) A metal such as zinc reaches a minimum solubility at a specific pH, and further additons of hydroxide can cause the zinc to become more soluble. Trivalent chrome behaves the same way, but requires a different pH to achieve minimum solubility. When there is a mixture of these metals it is not possible to precipitate them both to low levels. The following graph (published by the EPA) illustrates this relationship.

Precipitation of metal salts versus pH

(3) It has also been found that materials such as oils and grease, soaps or other organics, can interfere with the separation of the hydroxide precipitate from the water effluent.

(4) Particularly important, chelating or complexing agents, which tend to prevent precipitation of the hydroxides, sometimes are present in the waste water.

Another problem is that some metals require a very high pH to precipitate as hydroxide to low levels, the effluent water must then be neutralized before it can meet discharge pH limitations.

6. What are the chelating or complexing agents and how do we know if they are present?

Materials such as "EDTA", gluconates, ammonia complexes, Rochelle salts etc., are often added to plating solutions to keep the heavy metals in solutions. In many cases, when plating operators purchase proprietary solutions from supplers, the chemical compositions are not provided. An analysis may be made for a total organic content or an attempt to indicate whether or not such materials are present. But normally it is necessary to experimentally determine how completely the metals are precipitated.

7. Are the metal sulfides a great deal less soluble than the metal hydroxides?

Yes, as can be seen from the following table:

Approximate Solubilities of Metals
ppm in pure water

Metal	As Hydroxide	As Sulfide	Factor*
Iron	5×10^{1}	1×10^{-4}	5×10^{5}
Zinc	3×10^{2}	1×10^{-6}	3×10^{8}
Cadmium	3×10^{0}	1×10^{-6}	3×10^{6}
Nickel	7×10^{1}	6×10^{-8}	1×10^{7}
Copper	2×10^{-2}	2×10^{-13}	1×10^{11}
Lead	2×10^{0}	6×10^{-9}	3×10^{8}
Mercury	6×10^{-4}	1×10^{-21}	6×10^{17}
Silver	2×10^{1}	4×10^{-12}	5×10^{12}
Chromium	1×10^{-3}	(No Precip)	

$$\text{Factor} = \frac{\text{Solubility as Hydroxide}}{\text{Solubility as Sulfide}}$$

Kep data from 11th edition of Lange's Handbook was used to calculate solubilities.

8. Why has sulfide precipitation of heavy metals not been favored over hydroxide precipitation?

Because, as a practical matter, most waste water streams are subject to variations in both flow rates and metal concentrations and there is no practical way to add the exact amount of soluble sulfide for corresponding to the metal to be precipitated. If too little is added, all the metal will not be precipitated. If too much is added, the excess sulfide will be in the water effluent, and there can be a problem with the evolution of H_2S gas which has an objectionable odor and can be toxic above certain concentrations.

9. How does the Permutit Sulfex Process overcome the problem of supplying a sufficient amount of sulfide without allowing excess sulfide to discharge with the water or into the air?

It turns out to be relatively simple, considering the solubility and chemistry of iron sulfide. Knowing the expected flow rate of the heavy metal to be precipitated, an excess amount of sulfide is provided so that under normal conditions, all of the heavy metal can be converted to a sulfide. Iron is also provided in a quantity so that all of the sulfide added can be precipitated as iron sulfide. To the extent that there is any excess iron in the waste, this is precipitated as iron hydroxide by maintaining the pH results in the [illegible] range. Under these conditions there is no significant discharge of soluble sulfide or iron with the water effluent and no appreciable rate of H_2S.

If there is a temporary increase in the amount of heavy metal running into the treatment system, so that the heavy metal requires more sulfide than the amount being added, sulfide will be withdrawn from excess iron sulfide sludge maintained in the system.

In practice, the sulfide normally is added as a mixture made from sulfide precipitate which in some respects can be compared with a dispensable ion exchange resin for critical soluble heavy metals from the waste water. It is not necessary to match the addition rate of the iron sulfide exactly with the flow rate of heavy metals so long as some excess iron sulfide and iron hydroxide is normally removed with the sludge.

10. How is the capture of the very small or near colloidal precipitates controlled in the Permutit Sulfex Process?

Generally the well demonstrated Permutit Precipitator sludge blanket clarifier is used to continuously remove suspended and near-colloidal particles from the raw water.

For low flow rates, another type of filter may be selected. A polishing filter often is specified to give further assurance that the effluent is sparkling clear and free of waste solids.

The Permutit Company, Inc., has a great deal of practical experience in removing suspended solids and near-colloidal materials from raw water and waste water. This experience forms an important basis for the Permutit Sulfex Process.

11. What levels of heavy metal removal have been achieved using the Permutit Sulfex Process?

Levels under [illegible] ppm have been achieved for all heavy metals and levels down to [illegible] ppm with some. It should be noted that these are normal conditions at work affecting the extent of metal removal including the presence of chelating agents.

12. Are all chelating agents equally troublesome?

No, the low solubilities of the metal sulfides can overwhelm the presence of most commonly used chelating agents. Not all metals respond the same. In some tests, sulfide precipitated copper in the presence of ammonium, gluconate, pyrophosphate, citrate, and Rochelle salts to levels of 0.01 - 0.02 ppm. Under comparable conditions with citrate, the level was 0.16 ppm, and with EDTA it was 1.7 ppm. However, with more effluent contact with iron sulfide solids, the effluent level was maintained under 0.1 ppm, even in the presence of EDTA.

13. How do such numbers compare with levels achievable by the hydroxide process?

Under comparable test conditions above, the copper was 2.3 ppm with citrate and 2.6 ppm with EDTA and 0.1 ppm with pyrophosphate. In general, the levels achieved by sulfide precipitation are lower than the levels achieved by hydroxide precipitation.

The most dramatic difference occurs when hexavalent chrome is in the waste water. In this case the hydroxide process fails completely to remove chrome. The sulfide process typically gave test levels of chrome under 0.05 ppm. Even when EDTA was also present, the chromium was reduced to 0.1 ppm or less.

14. How does the Permutit Sulfex process work so well when the chromium is initially present as a chromate in the hexavalent condition?

The Sulfex reagent, iron sulfide, has the ability to reduce hexavalent chrome by the following reaction:

$$CrO_4^{=} + FeS + 4\,H_2O \rightarrow Fe(OH)_3 + Cr(OH)_3 + S^{0} + 2\,OH^{-}$$

Note that chromium precipitates as the hydroxide rather than the sulfide.

15. Does this mean that the chromate bearing solutions do not have to be isolated and treated separately when the Sulfex process is used?

Yes.

16. What kind of guarantee will Permutit make regarding its Sulfex Process?

Permutit will guarantee the chemistry of the process and the workability of the equipment supplied, based on certain input conditions as agreed upon, but obviously, Permutit cannot be responsible for the day-to-day operation of the equipment or a failure to meet quantitative limits that may be imposed by regulatory agencies. Where there is any question regarding the presence of chelating agents, or other organics that might interfere with the process, laboratory tests and in some cases pilot plant tests are recommended.

17. Is there a charge for laboratory tests or a pilot plant?

Yes. Permutit charges a nominal fee for a laboratory study and a rental fee for pilot plant equipment. Usually, if equipment is subsequently purchased, the charges for a laboratory study or pilot study will be refunded.

18. What is the cost and the availability of the chemicals required?

The iron sulfide slurry used in the Permutit Sulfex Process is normally made from ferrous sulfate, a soluble sulfide, and lime. The quantities needed are relatively small compared to their great availability. Either sodium hydrosulfide or sodium sulfide, and either lime or sodium hydroxide, may be purchased. Costs should be established through local chemical suppliers.

19. How does the cost of operating the Permutit Sulfex Process compare with the cost of operating hydroxide process?

The cost of the chemicals can be significantly less for the Sulfex Process under certain conditions. For instance, when hexavalent chrome must be treated, the simplicity of the one-step operation is much better than the alternative of sequentially using acid, sulfur dioxide, and lime.

The cost of operating the hydroxide process depends both on the total water flow and the metal concentration. In many cases, a great deal of lime is required simply to achieve the high pH, after which acid must be added to reduce the pH to an acceptable level for discharge. Note that where one unit of hydroxide is required to change the pH from 7 to 8, 1,000 units are required to achieve a pH of 11.

In both the hydroxide process and the Permutit Sulfex Process, comparable facilities are needed to add the reactant chemicals and separate the resulting sludge.

Copyright, The Permutit Co., Inc., 1976

20. What about sludge disposal from the Permutit Sulfex Process?

The sludge produced is a mixture of metal sulfides and hydroxides in a flocculated, dewaterable condition. The metal sulfides are very insoluble, and chemically equivalent to many of the naturally occurring metal ores that comprise part of the land mass. However, it is recommended that the sludges should be disposed of where they will not be washed into surface water or contacted with inorganic acids. A land-fill disposal site is normally preferred. Permutit also supplies sludge dewatering equipment.

21. Can heavy metals be recovered from the sulfide sludge?

In some cases, this probably could be justified. However, the Permutit Company has not been involved in this.

22. If a plant has existing facilities for operating the hydroxide process, can they be converted to handle the Permutit Sulfex Process?

In many cases, yes. There are options of utilizing available equipment for the Sulfex Process, or alternatively to add new facilities for the Sulfex Process to treat the effluent from the hydroxide process. Each case should be considered separately.

23. Are there any patent royalty charges relative to the Permutit Sulfex Process?

Yes, but Permutit is primarily interested in selling the specialized equipment related to the Permutit Company experience. However, a royalty charge has been established which is intended to be relatively small compared to the advantages of the Sulfex Process.

24. What are the royalty charges?

For low flow rates, there is a minimum charge currently set at $365 per year. For higher flow rates, where continuous flow equipment would normally be used, the annual charge is computed from the design flow basis. The cost diminishes from about $0.10/1,000 gal. at 25 gpm to under $0.02/1,000 gal. at high flow rates, as determined by an exponential equation. Consult your product specialist for the exact charge.

25. Please review the benefits of Sulfex Process.

Performance: The metal residuals in the effluent are normally lower than can be obtained by the hydroxide process, due to the lower solubility of the metal sulfides and the better ability to overcome most of the chelating or complexing agents.

Cost: The chemical cost may be significantly less, depending on the quantity and types of metal or metals to be treated. This is because hexavalent chrome can be reduced and removed in one step along with other metals and it does not have to be segregated for reduction pretreatment. Also, because sulfides can be precipitated in the pH range of 8-9, it is not necessary to purchase additional lime to achieve the higher pH's required for hydroxide precipitations and additional acid to lower the pH of the liquid effluent before discharge.

26. Are there any disadvantages to the Sulfex Process?

Care must be taken to prevent acids and the sulfides from combining with the release of H_2S, but it is not difficult to maintain this care and prevent odor emission.

Also, since the process is more effective than hydroxide systems, the total weight of sludge to be disposed of is greater, but where wasteful quantities of heavy metal are not being discharged to the sewer, the total amount of sludge produced is relatively unimportant.

27. What if there are cyanides present in the waste stream?

The Sulfex Process is strictly a heavy metal removal system. Any cyanides must be oxidized in a pretreatment step before they are introduced to the sulfex reaction. The Permutit Company can furnish the cyanide destruct system.

28. If new regulations are put into effect requiring a still lower level of discharge, or a "zero discharge", will the Sulfex Process be obsolete?

No. After the heavy metals have been removed by the Sulfex Process, the effluent can be further treated by ion exchange to remove soluble salts, or, treated by reverse osmosis facilities to produce a water which can be recycled within the operation.

29. What data should be collected to allow a proposal to be made for a Permutit Sulfex Process?

1. Nature of the business that generates the waste water.
2. The hours the plant operates per-day. The days the plant operates per-week.
3. List the various process lines and if possible provide a simple flow sketch of them.
4. List the average flow rates of rinse waters from each process line. Provide best possible estimate of the maximum flow the system must handle.
5. How many dump tanks does plant have? What is the volume of each tank? What is the dump frequency for each tank?
6. Include analyses of all rinse waters and dump tanks showing concentrations of all metals which must be removed. Dump tank analyses should be representative of the composition at time of dump or plant should extrapolate present analytical data to represent composition at time of dump.
7. If oil or soap is present in waste waters, this information should be included with relevant analyses.
8. Are chelating agents present? How much? What kind?
9. Will plant management submit design data to environmental authorities or have this data submitted by an outside consultant?
10. Effluent quality requirements will vary depending on where treated waste is discharged. If discharge is to a city sewer be sure to check with the city authorities. If discharge is directly to a river or stream, check with state authorities. What are the allowable effluent quality standards for the plant's wastes?
11. If treated waste water is to be recycled, what quality water is required? (Specifically the permissible dissolved solids content).
12. All waste treatment systems must be designed to "fail safe". In this respect transfer pumps, sump pumps, chemical feed pumps and mixers can be critical items. Repair or maintenance of this equipment should be considered because the treatment system can not function unless all pumps and mixers are operating. Does user plan to shut plant down for maintenance? Does user want all pumps duplicated or does user prefer to stock spare equipment?

30. Are there any further questions?

We know that we did not answer all your questions. Permutit specialists in the Sulfex process are available to you for technical assistance on the application and design of treatment systems. As mentioned, the analytical, laboratory and pilot plant test facilities of the Permutit R and D Center are also available should they be needed.

An EPA Demonstration Plant For Heavy Metals Removal By Sulfide Precipitation

Murray C. Scott*

The Holley Carburetor Company, a Division of Colt Industries, Paris, Tennessee was awarded a grant by the EPA to demonstrate the effectiveness of a new approach to removal of heavy metals from waste streams by sulfide precipitation. The process, called Sulfex™, was developed by the Permutit Company. Before the process was demonstrated at Holley Carburetor, preliminary pilot plant work was done by the Permutit Company at their research facilities. The work was done under a grant made to the National Association of Metal Finishers by the EPA.

The surfaces of the carburetor castings are of either zinc or aluminum and are chemically treated according to finishing specifications established by the automotive industry. A "Udylite" automatic rack line dips the castings into various treatment and rinse water tanks according to a pre-arranged program. The water rinses following the treatment tanks are the source of contaminated wastewater which must be treated before discharge into the city of Paris sewer system. Figure No. 1 illustrates the automatic line. Rinse flow is on the order of 35 gpm.

There are three basic cycles of treatment: (1) zinc chromate, (2) deoxidize, (3) aluminum chromate. Composite samples of rinse water were collected during each cycle and analyzed. The analytical results obtained are shown in Table No. 1. For design purposes these concentrations were increased by 20% as a factor of safety.

Two metals, chromium and zinc, had to be removed before discharge of this waste into the city sewer. Total zinc was not to exceed 0.10 mg/l and total chromium was not to exceed 1.0 mg/l. These were the effluent limits prescribed by Holley Carburetor in their bid specifications. Whether conventional "lime and settle" would meet these effluent limitations was questionable, as shown by solubility curves for zinc and chromium hydroxides in Figure No. 2.

The amphoteric properties of metal hydroxides frequently make the results of the "lime and settle" approach questionable. An operating pH ideally suited for good removal of one metal causes another metal to go

into solution. The solubility curves shown in Figure No. 2 suggest that the pH best suited for removal of zinc is about 10.0. At this pH (10.0) chromium has a solubility of about 5.0 mg/l, well above the maximum limit specified for this meal. The relationship of the solubilities of chromium and zinc shown in Figure No. 2 are used only to illustrate potential problems that might occur. These solubilities will vary with composition of the waste, but, the amphoteric properties of the precipitated metal hydroxides are forever present. However, if the heavy metals could be precipitated as sulfides, a mixture of metals would not be competing for optimum pH values. Comparison of the solubilities of various metal hydroxides and metal sulfides is shown in Figure No. 3. Not only are the metal sulfides not amphoteric, their solubilities are theoretically orders of magnitude below the metal hydroxides and decrease further with increasing pH.

THE SULFEX™ PROCESS

The Sulfex process uses an insoluble salt as the source of the sulfide ion. Selection of the salt is not random. The solubility of the insoluble salt must be greater than the solubility of the heavy metal sulfide to be precipitated. As indicated in Table No. 2, ferrous sulfide is more soluble than the heavy metal sulfides that would be precipitated from metal finishing waste streams, so the Sulfex process uses ferrous sulfide as the source of sulfide ions.

Solubility products are taken from 11th edition of Lange's Handbook of Chemistry.

The iron sulfide works best when it is a freshly prepared slurry. For practical reasons, pulverized iron

Fig. 3—Solubilities of Metal Hydroxides and Sulfides.

TABLE II
SOLUBILITY PRODUCTS

	Hydroxide	*Sulfide*
Iron	8.0×10^{-16}	6.3×10^{-18}
Zinc	1.2×10^{-17}	1.6×10^{-24}
Cadmium	2.5×10^{-14}	8.0×10^{-27}
Nickel	2.0×10^{-15}	3.2×10^{-19}
Copper	2.2×10^{-20}	6.3×10^{-36}
Lead	8.0×10^{-20}	1.2×10^{-15}
Mercury	3.0×10^{-26}	1.6×10^{-52}
Silver	2.0×10^{-8}	6.3×10^{-50}

sulfide is not used. Since only the surface of the large particle is useful, much of the iron sulfide particle would be wasted. However, freshly precipitated iron sulfide has a great deal of reactive surface. Quantities of iron sulfide required to adequately remove metals from waste streams will vary from 1.2 times stoichiometric to 3.0 times stoichiometric.

Characteristics of the Sulfex[15] process, when properly applied, offer a high degree of flexibility. Because of the low solubility of iron sulfide, the sulfide ion concentration is constantly maintained at about 0.02 ppb. Yet sufficient sulfide is available to accommodate wide variations in influent metal concentrations because the sludge blanket in the clarifier contains a large quantity of active iron sulfide. There is the additional asset of being able to reduce and remove hexavalent chromium in one step. The chemistry of the Sulfex process may be illustrated by two equations:

(1) $Cu(OH)_2 + FeS \rightarrow CuS + Fe(OH)_2$

(2) $Na_2CrO_4 + FeS + 4H_2O \rightarrow$
$Cr(OH)_3 + Fe(OH)_3 + 2NaOH + S$

Because of the low concentration of sulfide ion, soluble sulfide complexes do not form with mercury, tin or silver as shown in the following equations:

$$HgS + S^{=} \rightarrow HgS^{=}_2$$
$$SnS_2 + S^{=} \rightarrow SnS_3^{=}$$
$$Ag + S^{=} \rightarrow AgS^{-}$$

WASTE TREATMENT SYSTEM

The waste treatment system is designed to handle a maximum flow of 35 gpm. The operating day is 16 hours. A schematic of the system is shown in Figure No. 4. The treatment consists of neutralization, precipitation, clarification, filtration and sludge dewatering.

All rinse water comes into a two-compartment basin. The first compartment has a retention time of 105 minutes and the second compartment which normally operates with an average depth of 3 ft. has a detention time of about 80 minutes. The second compartment is operated at a low level so that it may accommodate filter backwash. These two holding compartments help equalize the waste but their primary function is to permit neutralization to a pH of about 8.5. Neutralization is done in two steps by the addition of lime which is controlled in both steps by pH sensing devices. The lime metering pump in the first step operates on-off. In the second step the lime metering pump has electronic stroke

Fig. 4

Fig. 5—Average pH Value of Raw Influent, Neutralization Stage I and II, and Precipitator Effluent as a Function of Time.

adjustment which is controlled by degree of deviation from the pH set point. Figure No. 5 shows comparative pH data for the raw waste, 1st stage neutralization, 2nd stage neutralization, and treatment plant effluent. The pH of the precipitator influent was closely controlled, ranging between a high of 9.0 and a low of 8.3; however, after the system was stabilized the pH was usually between 8.3 and 8.7. (The reduction of hexavalent chromium in the clarifier (precipitator) raised the pH and produced effluent pH values generally between 8.4 and 9.6).

Neutralized waste is then pumped to the clarifier where an iron sulfide slurry and a polymer are added. The rate of addition is proportional to influent flow. Jar tests are made twice each shift to determine the iron sulfide and polymer requirement. Timers on the panel board are then adjusted to change the cycle of the chemical feed pumps. The stroke of the pumps may also be changed, if desired, giving further flexibility to control of the chemical feeders.

The clarifier is a sludge blanket type, as illustrated in Figure No. 6. A slowly rotating mixer beneath the curtain baffle promotes floc formation. The floc mixture passes beneath the baffle into a section where the rise rate diminishes as the top of the unit is approached. This produces a blanket with a relatively sharp line of

Fig. 6

Fig. 7—Effect of Variable Ferrous Sulfide Requirement on the Reverse Ferrous Sulfide Capacity of the Sludge Blanket as a Function of Time.

Note: X's are points where no jar test was made.

demarcation between the top of the blanket and the clear water above the blanket. This blanket of suspended solids, which will range in concentration from 5000 mg/l to 15,000 mg/l, may consist of as much as 50% active iron sulfide. It is this reservoir of iron sulfide which allows the system to accommodate wide variations of influent metal concentrations with no change in the effluent quality.

To illustrate the effect of the iron sulfide reservoir in the sludge blanket, we ran jar tests on grab samples taken from the second neutralization basin to determine the amount of sulfide required. The yellow color of the chromate in the sample was used as an indicator. Source of the iron sulfide for this test was slurry taken from the chemical feed tank. When sufficient iron sulfide slurry has been added to react with all the metals and the hexavalent chromium in the sample, the yellow color disappears. The required iron sulfide dosage indicated by the jar test and the amount of iron sulfide being introduced by the chemical feed system at that time were noted and plotted on the graph shown in Figure No. 7.

Those areas with diagonal lines represent times when the actual feed of iron sulfide exceeded the demand, so active iron sulfide was accumulating in the sludge blanket. The dotted areas represent times when the actual demand from iron sulfide exceeded the feed rate, so active iron sulfide from the sludge blanket was being consumed. Total detention time of iron sulfide in the sludge blanket is about 19 hrs.

The amount of active iron sulfide in the sludge blanket

Fig. 8—Theoretical Ferrous Sulfide Requirement Compared with Jar Test Requirement as a function of Time.

Note: X's are points where no jar test was made.

can be controlled by adjusting the rate of feed of the iron sulfide slurry; however, excessive feed rates will increase chemical operating costs. For this reason, we were interested in stoichiometric iron sulfide requirements. The waste was analyzed for metals and then the stoichiometric sulfide requirement was obtained by calculation. A comparison of stoichiometric sulfide requirement and the sulfide requirement indicated by jar testing is shown in Figure No. 8. The jar test sulfide demand varied from 200% to 500% of the theoretical, averaging about 3.5 times stoichiometric. With more operating experience, closer control is expected to reduce the iron sulfide consumption.

The clarifier has a sludge concentrator which is blown off automatically, based on influent flow to the clarifier.

Since the amount of blowoff required is a function of both the hydraulic load and the suspended solids load, the blowoff rate is further controlled by adjusting a timer which determines the length of time the blowoff valve is open. This is estimated by collecting a sample from the unit to determine the height of the sludge blanket in the tube settlers. Two sampling points, one within the tube settlers and one six inches below the tube settlers, permits the operator to determine whether the blanket is too high or too low.

The blowoff is collected in a sump and then pumped through a filter press for dewatering. A polypropylene filter cloth is used. No precoat or body feed is required. Operation is at constant pump drive speed until the pressure builds up to 50 lbs. At this pressure, the resulting cake breaks away cleanly from the cloth. Down time is about 10-15 minutes. Operating time is about 10-14 hours. The unit holds slightly over 5 cu. ft. Dewatered cake is disposed at a local landfill.

The feed to the press contained from 14,000 mg/l to 24,000 mg/l suspended solids. Effluent from the press contained about 3 mg/l suspended solids at the beginning of the run and 22 mg/l at breakthrough (at end of run). Filter cake contained about 25% solids. On a total dry weight basis, the percentages of metals in the filter cake are shown in Table No. 3

The Sulfex process produces more sludge than a conventional "lime and settle" process, because a mole of insoluble ferrous hydroxide is produced for each mole of heavy metal sulfide formed. The excess iron sulfide in the clarifier sludge blanket also adds to sludge volume. This must be taken into consideration and adequate sludge disposal included as part of the overall design of the Sulfex treatment system. For example:

When designing a conventional rinse water waste

TABLE III

Cr	3.3% to 4.5%
Fe	26.9% to 33.0%
Cu	<0.1%
Zn	3.7% to 4.1%
Total Solids	23.4% to 29.3%

treatment system, the waste is usually neutralized before clarification. The addition of iron sulfide to the clarifier converts this treatment system to the Sulfex™ process. This method of applying the Sulfex process results in a substantial increase in sludge production (on the order of 2.8 times) over straight lime treatment. It can only be justified where total metal concentrations are very low, or where there is inadequate space to permit a Sulfex polishing system.

A Sulfex polishing system uses a second clarifier. Iron sulfide and a polymer are added to this clarifier. Chemical requirements are quite low, since only residual metals from the hydroxide process need be treated. In applications of this type, the amount of additional sludge produced by the Sulfex process usually will amount to only 1% to 2% of the total sludge produced by the entire treatment system.

Supernatant from the clarifier is then pumped to a dual media, anthracite-sand, filter which is equipped with an air scour to insure good cleaning during the backwash procedure. Prudence, sound engineering, and requirement of a performance guarantee make filtration mandatory, but excellent quality is possible without filtration, as illustrated in Table No. 4.

TABLE IV

Metal	*Clarifier Effluent mg/l*	*Filtered Effluent mg/l*
Zn	0.1 to 0.5	≤ 0.05
Fe	0.3 to 4.0	≤ 0.50
Cu	≤ 0.01	≤ 0.01
Cr (Total)	0.1 to 1.0	≤ 0.04
Cr^{+6}	≤ 0.05	≤ 0.04
Total Suspended Solids	1.0 to 10	≤ 0.5 - 1.0

Filtered effluent from the treatment system at Holley Carburetor routinely produced metal concentrations lower than detectable by today's accepted analytical methods. Metal concentrations in the influent and effluent are shown in Figures No.'s. 9, 10, 11, 12, 13.

CHEMICAL OPERATING COSTS

Detailed data was collected over a period of 38 shifts (19 days). This included the startup period when all equipment was checked out and plant personnel were being trained. About 22 shifts (11 days) were required to reach a steady state where operating conditions were considered normal. For this reason only, data collected during the last 16 shifts (8 days) were used for calculating chemical operating costs. During this period, the flow averaged 26 gpm. Metal concentration averaged 34 mg/l Cr^{+6} and 34.7 mg/l Zn. The pH ranged between 5.2 and 6.5

Unit cost for chemicals were as follows:

Ferrous Sulfate	6.75¢/lb
Sodium Sulfhydrate	26.5¢/lb
Lime	4.65¢/lb
Polyelectrolyte	105.0/lb

The total chemical cost per shift is shown in Figure No. 14.

Comparison of the stoichiometric iron sulfide demand for zinc and hexavalent chromium can be used to give a chemical operating cost value to each. The total average chemical cost per shift was $18.50. The kilograms of dry solids produced per shift was 3.24 of which 1.6 kg contains chromium and 1.63 kg contains zinc.

$$\frac{\text{Stoichiometric FeS Requirement for } Cr^{+6}}{\text{Stoichiometric FeS Requirement for } Cr^{+6} + Zn} = Cr^{+6} \text{ fraction}$$

$$\frac{1.67 \text{ kg FeS/kg } Cr^{+6}}{3.01 \text{ kg FeS/kg } Cr^{+6} + Zn} = 0.555, Cr^{+6} \text{ fraction}$$

$$1.0 - 0.5548 = 0.4452, \text{ Zn fraction}$$

$$\frac{0.5548 \times \$18.50}{1.61 \text{ kg}} = \$6.38/\text{kg } Cr^{+6}$$

$$\frac{0.4452 \times \$18.50}{1.63} = \$5.05/\text{kg Zn}$$

Fig. 14—Total Chemical Cost as a Function of Time.

COMPARATIVE CHEMICAL COSTS FOR CONVENTIONAL TREATMENT

Conventional treatment would consist of the addition of sulfuric acid to reduce the pH to 2.0, the addition of sodium bisulfite to reduce the chromium, followed by lime for neutralization and precipitation of the metal hydroxides. Unit costs for chemicals obtained locally are:

Bisulfite	23¢/lb	($0.5072/kg)
Sulfuric Acid	4.65¢/lb	($0.1025/kg)
Hydrated Lime	4.65¢/lb	($0.1025/kg)
Polyelectrolyte, anionic	225¢/lb	($4.96/kg)

The theoretical requirements to remove one kilogram of hexavalent chromium would be as follows:

(1) Bisulfite - 3 Kg $NaHSO_3$ is required to reduce 1 Kg Cr^{+6}. Since an excess of about 50% over stoichiometric is normally required, the amount of $NaHSO_3$ needed is:

$$3 \text{ Kg } NaHSO_4 \times 1.5 = 4.5 \text{ Kg } NaHSO_3/\text{kg } Cr^{+6}$$

(2) Sulfuric Acid - To acidify the waste water from pH 5.5 to 2.0 - 2.5 requires 516 mg/l 66° Be H_2SO_4, thus:

$$\frac{1 \text{ liter}}{34 \text{ mg } Cr^{+6}} \times \frac{10^6 \text{ mg}}{\text{kg}} = \frac{29{,}411 \text{ liters}}{\text{kg } Cr^{+6}}$$

$$\frac{29{,}411 \text{ liters}}{\text{kg } Cr^{+6}} \times \frac{5.16 \times 10^{-4} \text{ kg}}{1} = 15.18 \text{ kg/kg } Cr^{+6}$$

The stoichiometric requirement of H_2SO_4 for reduction of chromium is 1.42 kg H_2SO_4/Kg Cr^{+6}, therefore, the total acid requirement is:

$$15.18 \text{ kg} + 1.42 \text{ kg} = 16.6 \text{ kg/kg } Cr^{+6}$$

(3) The hydrated lime required to bring the pH back to 8.0 - 9.0 is 750 mg/l as $Ca(OH)_2$. Translating to kg/kg Cr^{+6}:

$$\frac{1 \text{ liter}}{34 \text{ mg } Cr^{+6}} \times \frac{10^6 \text{ mg}}{\text{kg}} = \frac{29{,}411 \text{ liters}}{\text{kg } Cr^{+6}}$$

$$\frac{29{,}411 \text{ liters}}{\text{kg } Cr^{+6}} \times \frac{7.5 \times 10^{-4} \text{ kg}}{1} = 22 \text{ kg/kg } Cr^{+6}$$

(4) Polyelectrolyte - Anionic polyacrylamide polymers are frequently used at dosages of about 1 mg/l, thus:

$$\frac{29{,}411 \text{ liters}}{\text{kg } Cr^{+6}} \times \frac{1.0 \times 10^{-6} \text{ kg}}{1} = 0.03 \text{ kg/kg } Cr^{+6}$$

Summarizing the chemical costs:

Bisulfite	= 4.5 kg × $0.507 = $2.28/kg Cr^{+6}
Sulfuric Acid	= 16.6 kg × $0.103 = $1.71/kg Cr^{+6}
Hydrated Lime	= 22 kg × $0.103 = $2.27/kg Cr^{+6}
Polyelectrolyte	= 0.03 kg × $4.96 = $0.15/kg Cr^{+6}
Total Chemical Cost	= $6.41/kg Cr^{+6}

Comparing the chemical costs for treatment of this waste by conventional methods with chemical costs for treatment by the Sulfex process is difficult, but the following data is a reasonable estimate:

TABLE V

	Conventional	*Primary Sulfex*	*Polishing Sulfex*
For Chromium	$6.41/kg	$6.38/kg	$6.39/kg
For Zinc	0.17/kg	5.05/kg	.17/kg
For Sludge Disposal	1.16	2.32	1.88
Total	$7.74	$13.75	$8.44

With this particular waste, a portion of the sludge comes from precipitation of phosphate. Unfortunately, we did not collect detailed analytical data on phosphate concentrations because removal of phosphate was not required. The original analytical data showed a low phosphate concentration of 38 mg/l as P and a high of 65 mg/l as P. The low concentration was used for estimating the sludge produced by phosphate precipitation and the value was included in the assessment of comparative sludge disposal costs.

Increased chemical usage and increased sludge is the premium paid for primary Sulfex treatment where the FeS is added to the same clarifier that would be used for conventional hydroxide precipitation. The third column in Table No. 4 shows costs for chemicals and sludge disposal for a complete treatment system which includes polishing by the Sulfex process.

COST ANALYSIS

Operating Costs

The yearly operating cost, excluding depreciation and licensing fees, for the treatment system at Holley Carburetor is outlined below. This cost results from charges incurred by operators, utilities and chemicals.

The estimated yearly operating cost, based on plant performance to date, is as follows:

1. Operators Salaries:

$10,800 per operator × 2 operators = $21,600
+ fringe benefits at 40% = 8,640

Total Salaries = $30,240/year

2. Electricity:

$$\frac{203.32\ \text{kwh}}{\text{day}} \times \frac{5\ \text{days}}{\text{wk}} \times \frac{52\ \text{wk}}{\text{yr}} \times \frac{\$0.0191}{\text{kwh}} \quad \$1010/\text{year}$$

3. Water:

$4162\ m^3 \times \$0.053/m^3$ = $220/year

4. Chemical:

$$\frac{\$14.69}{\text{shift}} \times \frac{2\ \text{shifts}}{\text{day}} \times \frac{260\ \text{days}}{\text{yr}} = \$7639/\text{year}$$

5. Sludge Handling and Disposal Cost:

$$\frac{\$15}{\text{day}} \times \frac{260\ \text{days}}{\text{yr}} = \$3900/\text{year}$$

Total Operating Cost is therefore:

Salaries	=	$30,240
+ Electricity	=	1,010
+ Water	=	220
+ Chemicals	=	7,639
+ Sludge Disposal	=	3,900
TOTAL		$43,009/year

Capital costs are itemized as follows:

Equipment	$92,465
Engineering Costs (Consulting, report to state and design for underground tanks)	17,400
Underground Tanks	48,000
Shipping and Installation	21,730
Taxes (on equipment only)	1,089
	$180,684

SUMMARY

Precipitation of heavy metals by sulfide will in most cases permit any plant to economically meet extremely rigid discharge standards but frequent complaints are lodged that disposal of sulfide sludges presents a serious impediment to acceptance of any sulfide process for heavy metals removal. The complaints are not necessarily on solid ground.

In almost all cases the waste streams are neutralized with lime or caustic. This results in the precipitation of metal hydroxides. The next logical step is to remove these precipitated metals by coagulation and settling or any other technique that might be applicable. Sulfide precipitation, if required, should be applied to residual soluble metals which represent a very small portion of the total metals originally present in the waste streams. Is there any reason why this very small sludge portion consisting of metal sulfides cannot be disposed in the same manner as the large portion of metal hydroxides?

The leaching test procedure, described in the Dec. 18, 1978 Federal Register, page 58596, was used to obtain the following comparative data on a sludge produced by the Sulfex process and on a sludge produced by the addition

of lime. A solution containing 20 mg/l of each metal was used for the test. Equal portions of this solution were treated, one by Sulfex™ and the other by lime. The sludge produced by each procedure was then subjected to the leaching test recommended by the EPA. The pH of the Sulfex mixture was 5.7. The pH of the hydroxide mixture was 5.8.

The Sulfex mixture gave no odor of H_2S nor was there any evidence of H_2S detectable by lead acetate paper.

EXTRACT LEVEL mg/l

	EPA Proposed Regulation	*Sulfex*	*Hydroxide*
Arsenic	0.50		
Barium	10.0		
Cadmium	0.10	0.02	1000
Chromium (Total)	0.50	< 0.05	1.5
Lead	0.50	0.20	55
Mercury	0.02		
Selenium	0.10		
Silver	0.50	0.02	0.21
MAY BE CONSIDERED IN FUTURE			
Ni		35	>33
Fe	3	820	< 1
Zn	50	0.36	1475
Cu	10	0.03	259

These data would suggest that disposal of sulfide sludges will present no more of a problem than disposal of hydroxide sludges. Both appear to be material that should be disposed in a secure landfill.

Summary Report

Control and Treatment Technology for the Metal Finishing Industry

Sulfide Precipitation

April 1980

This report was developed by the
Industrial Environmental Research Laboratory
Cincinnati OH 45268

Sludge dewatering filter press

Overview

Today more than 13,000 firms in the United States are engaged either wholly or partially in electroplating or other metal finishing operations. These firms discharge their spent process water to either waterways or publicly owned treatment works (POTW's), and they comprise more individual wastewater discharges than any other industrial category. The pollutants contained in this process water are potentially toxic; therefore, to comply with the Clean Water Act of 1977 (Public Law 95-217), the water must be treated before being discharged to a waterway or a POTW. The regulations require oxidation of cyanide, reduction of hexavalent chromium, removal of heavy metals, and control of pH.

Sulfide precipitation is one among many methods available for removing metals from metal finishing process wastewaters. This summary report series presents information on various technologies that have been demonstrated. Other publications in the series discuss different control alternatives. By providing process descriptions, advantages and disadvantages, and economic characteristics of each system, these reports can facilitate the evaluation of effective means of pollution control by those involved in metal finishing wastewater pollution control.

Metals are usually removed by adding an alkali, such as hydrated lime [$Ca(OH)_2$] or caustic soda (NaOH), to adjust the pH of the wastewater to the point where the metals exhibit minimum solubilities. The metals precipitate as metal hydroxides and can be removed from the wastewater by flocculation and clarification. In many cases, the addition of a postfiltration step can reduce further the total metal concentration in the effluent by removing any metal hydroxide carryover.

Some common limitations of the hydroxide process follow:

- The theoretical minimum solubilities for different metals occur at different pH values (Figure 1). For mixtures of metal ions, it must be determined whether a single pH can produce sufficiently low, though not minimum, solubilities for the metal ions present in the wastewaters.
- Because hydroxide precipitates tend to resolubilize if the solution pH is increased or decreased from their minimum solubility points, maximum removal efficiency will not be achieved unless the pH is controlled within a narrow range.
- The presence of complexing ions—such as phosphates, tartrates, EDTA,[1] and ammonia—that are commonly found in cleaner and plating formulations may have an adverse effect on metal removal efficiencies when hydroxide precipitation is used. Figure 2 shows the solubility of nickel ions as a function of pH when precipitated with other metal ions in the presence of certain complexing ions used in a proprietary electroless nickel plating bath.

Despite these limitations, hydroxide precipitation (particularly when followed by flocculation and filtration) produces a high-quality effluent when applied to many waste streams. Often coprecipitation of a mixture of metal ions will result in residual metal solubilities lower than those that could be achieved by precipitating each metal at its optimum pH. In other cases, modification of the hydroxide process has improved its performance in treating waste streams containing complexed heavy metals. This improved performance is usually realized by dissolving another positively charged ion—such as Fe^{+2} or Ca^{+2}—into the wastewater and then precipitating the metals. High-pH lime treatment

Metal Solubility as a Function of pH

Figure 2.

Solubility of Complexed Nickel When Precipitated With Caustic Soda

and ferrous sulfate ($FeSO_4$) precipitation techniques use this principle.

Sulfide precipitation has been demonstrated to be an effective alternative to hydroxide precipitation for removing various heavy metals from industrial wastewaters. The high reactivity of sulfides (S^{-2}, HS^-) with heavy metal ions and the insolubility of heavy metal sulfides over a broad pH range are attractive features compared with the hydroxide precipitation process (Figure 3). Sulfide precipitation can also achieve low metal solubilities in the presence of certain complexing and chelating agents.

The main difference between the two processes that currently use sulfide precipitation is the means of introducing the sulfide ion into the wastewater. In the soluble sulfide precipitation (SSP) process, the sulfide is added in the form of a water-soluble sulfide reagent such as sodium sulfide (Na_2S) or sodium hydrosulfide (NaHS). A more recently developed process adds a slightly soluble ferrous sulfide (FeS) slurry to the wastewater to supply the sulfide ions needed to precipitate the heavy metals.

In the past, operational difficulties prevented more than minimal application of the SSP process. Recent investigations, however, have eliminated or reduced these problems. Technological advances in the area of selective-ion electrodes have provided a probe that

Note.—Plotted data for metal sulfides based on experimental data listed in Seidell's solubilities.

SOURCE: Solubilities for metal hydroxides are taken from curves by Freedman and Shannon, "Modern Alkaline Cooling Water Treatment," in *Industrial Water Engineering* (p. 31), Jan.-Feb. 1973.

Figure 3.

Solubilities of Metal Hydroxides and Sulfides as a Function of pH

has proven successful in pilot-scale evaluations for controlling the addition of soluble sulfide reagent to match reagent demand. Eliminating sulfide reagent overdose can prevent the odor problem commonly associated with these systems. In currently operated soluble sulfide systems that do not automatically adjust reagent dosage to match demand, the process tanks must be enclosed and vacuum evacuated to minimize sulfide odor problems in the work area. The formulation of polyelectrolyte conditioners that effectively flocculate the fine metal sulfide particles has eliminated the difficulty in separating the precipitants from the discharge and has resulted in sludges that are easily dewatered.

Recently, a patented sulfide precipitation process called Sulfex™ has proven effective in separating heavy metals from plating waste streams. The process uses a freshly prepared ferrous sulfide slurry (prepared by reacting $FeSO_4$ and NaHS) as the source of the sulfide ions needed to precipitate the metals from the wastewater. The process operates on the principle that FeS will dissociate into ferrous ions and sulfide ions to the degree predicted by its solubility product. As sulfide ions are consumed, additional FeS will dissociate to maintain the equilibrium concentration of sulfide ions. In alkaline solutions, the ferrous ions will precipitate as ferrous hydroxides. Because most heavy metals have sulfides less soluble than ferrous sulfide, they will precipitate as metal sulfides.

An advantage of the insoluble sulfide precipitation (ISP) process is the absence of any detectable hydrogen sulfide (H_2S) odor—a problem historically associated with SSP treatment systems. Another

Figure 4.

Wastewater Treatment Processes for Removing Heavy Metals: (a) Hydroxide Precipitation, (b) SSP, and (c) ISP

advantage is that the ISP process will reduce hexavalent chromium to the trivalent state under the same process conditions required for metal precipitation, thus eliminating the need to segregate and pretreat chromium waste streams. Disadvantages of the ISP process include considerably higher than stoichiometric reagent consumption and significantly higher sludge generation factors than either the hydroxide or soluble sulfide treatment processes.

Figure 4 compares typical process flow diagrams of a hydroxide treatment system and both types of sulfide systems. Most of the elements of the sulfide systems are common to the hydroxide precipitation treatment sequence. The sulfide treatment processes also can be used as a polishing system after a conventional hydroxide precipitation/clarification process to

significantly reduce the consumption of sulfide reagent.

The final selection of a hydroxide or sulfide process should also consider any different constraints for disposal of the resulting sludge. Preliminary studies have indicated that metal ion leachability is lower for metal sulfide sludges than for hydroxide sludges. However, the long-term impacts of weathering and of bacterial and air oxidation of sulfide sludges have not been evaluated.

At this time, the necessary precautions for environmentally safe disposal of sulfide sludge have not been established. This lack of information prevents an evaluation of the impact of generating a sulfide sludge instead of a hydroxide sludge.

This report will evaluate the sulfide precipitation process, assuming that disposal of the residue incurs the same constraints as the hydroxide process.

The importance of design safeguards to avoid the potential hazards associated with sulfide precipitation processes cannot be overemphasized. For example, a sulfide reagent coming into contact with an acidic waste stream can result in the evolution of toxic H_2S fumes in the work area. The potential danger can be minimized by fairly conventional design safeguards, but the safeguards must be well maintained to be effective. Another potential problem for plants discharging to enclosed sewers is the danger associated with residual levels of sulfide in the wastewater. This problem occurs primarily with the SSP processes because the low solubility of FeS in the ISP process controls the residual sulfide concentration at a very low level. Elimination of the H_2S hazard to sewer workers would require either oxidation of the wastewater before discharge or process controls to ensure a low sulfide residual in the discharge.

This summary report is intended to promote an understanding of the use of sulfide precipitation for the removal of heavy metals from industrial waste streams. The report includes a general discussion of sulfide precipitation process theory and an evaluation of both soluble and insoluble sulfide treatment systems in terms of state of development, performance, cost, and operating reliability.

Dual-bed effluent polishing filters

Process Theory

The precipitation of a dissolved metal ion as a metal sulfide (MS) occurs when the metal ion (M^{+2}) contacts a sulfide ion (S^{-2}):

$$M^{+2} + S^{-2} \rightarrow MS \downarrow$$

Most heavy metals encountered in electroplating wastewater will form stable metal sulfides; common exceptions include the trivalent chromic and ferric ions.

The two processes currently employed to precipitate metals as sulfides differ mainly in the method used to introduce the sulfide ions into the wastewater. The SSP process uses a water-soluble sulfide compound; consequently, the concentration of dissolved sulfide depends on the quantity of reagent added. The ISP process mixes the wastewater with a slurry of slightly soluble FeS, which will dissociate to satisfy its solubility product, yielding a dissolved sulfide concentration of approximately 0.02 ppb in the wastewater. Use of FeS as the source of sulfide ions controls the level of dissolved sulfide at a concentration low enough to eliminate any detectable emission of H_2S but still provide an inventory of undissolved sulfide that automatically replaces the sulfide consumed in precipitation reactions.

In the ISP process, the dissolved sulfide ions will precipitate as a metal sulfide any metal with a sulfide solubility less than that of FeS. As shown in Table 1, the only heavy metal with a sulfide more soluble than FeS is manganese. In an alkaline solution, the ferrous ions generated in the dissociation of the FeS will precipitate as hydroxides. Maintaining low levels of ferrous ions in the effluent requires that the pH be controlled between 8.5 and 9.5.

One advantage of the ISP process is the ability of the sulfide and ferrous ions to reduce hexavalent chromium to its trivalent state, which eliminates the need to segregate and treat chromium wastes separately. Under alkaline conditions, the chromium will then precipitate as chromium hydroxide [$Cr(OH)_3$]. The overall reduction reaction is:

$$H_2CrO_4 + FeS + 4H_2O \rightarrow Cr(OH)_3 \downarrow + Fe(OH)_3 \downarrow + S \downarrow + 2H_2O$$

Table 1.

Solubilities of Sulfides

Metal sulfide	K_{sp} (64° to 77° F)*	Sulfide concentration (mol/l)
Manganous sulfide	1.4×10^{-15}	3.7×10^{-8}
Ferrous sulfide	3.7×10^{-19}	6.1×10^{-10}
Zinc sulfide	1.2×10^{-23}	3.5×10^{-12}
Nickel sulfide	1.4×10^{-24}	1.2×10^{-12}
Stannous sulfide	1.0×10^{-25}	3.2×10^{-13}
Cobalt sulfide	3.0×10^{-26}	1.7×10^{-13}
Lead sulfide	3.4×10^{-28}	1.8×10^{-14}
Cadmium sulfide	3.6×10^{-29}	6.0×10^{-15}
Silver sulfide	1.6×10^{-49}	3.4×10^{-17}
Bismuth sulfide	1.0×10^{-97}	4.8×10^{-20}
Copper sulfide	8.5×10^{-45}	9.2×10^{-23}
Mercuric sulfide	2.0×10^{-49}	4.5×10^{-25}

*Solubility product of a metal sulfide. K_{sp} equals the product of the molar concentrations of the metal and sulfide.

Ferrous sulfide makeup and feed system

In the SSP process, the sulfide ion is capable of reducing hexavalent chromium as follows:

$$2H_2CrO_4 + 3NaHS + 8H_2O \rightarrow 2Cr(OH)_3 \downarrow + 3S \downarrow + 7H_2O + 3NaOH$$

The question of whether a soluble sulfide reagent can reduce and precipitate hexavalent chromium in one step was addressed in a pilot study conducted for the U.S. Navy. The study concluded that the reduction could be accomplished in the presence of ferrous ions (or conceivably some other suitable secondary metal). The ferrous ion acts principally as a catalyst for chromium reduction. Less than stoichiometric dosages[2] of iron are required to effect reduction of most of the chromium. Nearly stoichiometric dosages, however, are required to achieve levels typical of other reduction processes. No operating systems currently employ this one-step process.

[2]Stoichiometric dosage = dosage of reagent required per unit of contaminant based on the chemical formula and relative atomic weights as predicted by the treatment reaction.

SSP Process Chemistry

The addition of a sulfide reagent that has a high solubility in wastewater will yield a relatively high concentration of dissolved sulfide, compared with the ISP process. This high concentration of dissolved sulfide causes a rapid precipitation of the metals dissolved in the water as metal sulfides, which often results in the generation of small particle fines and hydrated colloidal particles. The rapid precipitation reaction tends more toward discrete particle precipitation than toward nucleation precipitation (the precipitation of a particle from solution onto an already existing particle). The resulting poor-settling or -filtering floc is difficult to separate from the wastewater discharges. This problem has been solved by the effective use, separately or combined, of coagulants and flocculants to aid in the formation of large, fast-settling particle flocs.

Another disadvantage of an SSP system is the H_2S odor often associated with it. The odor detection level of hydrogen sulfide—0.1 to 1.0 ppm—is very low compared with the workplace H_2S concentration limit of 10 ppm specified by the Occupational Safety and Health Administration (OSHA) for worker safety.

The rate of H_2S formation in a water solution is a function of pH

(concentration of hydrogen ions) and sulfide ion concentration. The formation of H_2S from dissolved sulfide ions proceeds as follows:

$$S^{+2} + H^+ \rightarrow HS^-$$

$$HS^- + H^+ \rightarrow H_2S$$

Actually, the strong base S^{-2} is not present in any significant amount except at high pH. For example, at a pH of 11, less than 0.05 percent of the dissolved sulfide is in the S^{-2} form; the remainder is in either the HS^- or H_2S form. Figure 5 is a graph for determining the percentage of the dissolved sulfide in the form of H_2S as a function of the pH of the solution. The relationship shows that at a pH of 9, H_2S accounts for only 1 percent of the free sulfide in solution. The rate of evolution of H_2S from a sulfide solution per unit of water/air interface will depend on the temperature of the solution (which determines the H_2S solubility), the dissolved sulfide concentration, and the pH. In practice, considering typical response lags of instruments and incremental reagent addition, control of the level of dissolved sulfide and pH would require fine tuning and rigorous maintenance to prevent an H_2S odor problem in the work area. In currently operating treatment systems, the H_2S odor problem is eliminated by enclosing and vacuum evacuating the process vessels.

Adding sulfide reagent to wastewater containing precipitated metal hydroxides will result in resolubilization of the metal hydroxides. The dissolving of the metal hydroxides occurs because the dissolved metal ion concentration is now lower than the equilibrium level predicted by the hydroxide solubility. These newly liberated metal ions will be precipitated by any excess sulfide present. The following reactions occur:

$$M^{+2} + S^{-2} \rightarrow MS \downarrow$$

$$M(OH)_2 \rightarrow M^{+2} + 2(OH)^-$$

$$M^{+2} + S^{-2} \rightarrow MS \downarrow$$

Note.—pK (logarithmic practical ionization constant) is used to measure the degree of dissociation of weak acids, in this case H_2S.

Figure 5.

Percent of Dissolved Sulfide in the H_2S Form

Normally, the precipitated solids are in contact with the wastewater long enough to result in an almost complete conversion of metal hydroxides to metal sulfides. Therefore, the sulfide reagent demand depends on the total metal concentration contained in a wastewater. Consequently, a significant reduction in sulfide reagent consumption could be achieved by separating the precipitated metal hydroxides from the wastewater before adding the sulfide reagent.

ISP Process Chemistry

The Sulfex™ process precipitates dissolved metals as sulfides by mixing the wastewater with an FeS slurry in a solid/liquid contact chamber. The FeS dissolves to

[a]x = stoichiometric equivalent concentration of FeS required to precipitate 20 mg Cu^{+2}/l = 27.7 mg FeS/l.

Note.—Results of jar tests with complexed Cu influent; pH values maintained between 7 and 8 during tests.

Figure 6.

Influence of FeS Dosage, Sludge Blanket Concentration, and Mixing Time on Copper Solubility

maintain the sulfide ion concentration at a level of 0.02 ppb.

The following reactions occur when FeS is introduced into a solution containing dissolved metals and metal hydroxide:

$$FeS \rightarrow Fe^{+2} + S^{-2}$$

$$M^{+2} + S^{-2} \rightarrow MS \downarrow$$

$$M(OH)_2 \rightarrow M^{+2} + 2(OH)^-$$

$$Fe^{+2} + 2(OH)^- \rightarrow Fe(OH)_2 \downarrow$$

The addition of ferrous ions to the wastewater and their precipitation as ferrous hydroxide [$Fe(OH)_2$] results in a considerably larger quantity of solid waste from this process than from a conventional hydroxide precipitation process.

As with SSP, the ISP process achieves an almost complete conversion of previously precipitated metal hydroxides to metal sulfides. The reaction goes to completion because of the long residence time of the solids in the treatment system before discharge.

Figure 6 shows three different factors that affect the ability of FeS

Note.—Results of hydroxide process jar tests with complexed Cu influent.

Figure 7.

Influence of $Ca(OH)_2$ Dosage, Sludge Blanket Concentration, and pH on Copper Solubility

to precipitate copper from a solution containing metal complexing compounds. The design criteria that must be addressed are:

- A dense sludge blanket must be maintained in the solid/liquid contact zone.
- Adequate mixing time is required for the precipitation reaction to reach equilibrium.
- From 2 to 4 times the required stoichiometric amount of reagent is needed to realize the low levels of dissolved copper achievable by sulfide precipitation.

To illustrate the relative effectiveness of sulfide precipitation, Figure 7 represents the solubility of copper in the same complexing compound solution as a function of pH. Even at a pH of 12, the level of dissolved copper cannot be reduced below 2 mg/l.

Hydroxide and sulfide mixer/clarifiers

Soluble Sulfide Precipitation

Use of a water-soluble sulfide compound to reduce the solubility of heavy metals in a wastewater discharge is an effective method of improving the performance of a hydroxide precipitation treatment system. This section describes the results of a recent investigation of the use of SSP and presents information on systems currently using the technology.

Pilot Plant Evaluation

Test Description. Currently, there are only a few applications of SSP to treat metal finishing wastewater. To provide a source of the data needed by firms interested in using the treatment process, the U.S. Environmental Protection Agency's (EPA's) Industrial Environmental Research Laboratory funded a pilot study by the Boeing Commercial Aircraft Company to compare and evaluate five treatment systems using variations of SSP and hydroxide precipitation processes to treat metal finishing wastewater. The pilot tests were designed to simulate the three basic process systems shown in Figure 8. The five process variations tested were:

- Lime only, clarified (LO-C)—the conventional process using lime as a neutralizing agent to precipitate the dissolved metals and clarification to separate the suspended solids from the discharge (System A)
- Lime only, clarified, filtered (LO-CF)—the LO-C process with a filtration step downstream of clarification to improve the suspended solids removal (System A)
- Lime with sulfide, clarified (LWS-C)—the LO-C process with controlled addition of a soluble sulfide reagent in the neutralizing chamber (System B)
- Lime with sulfide, clarified, filtered (LWS-CF)—the LWS-C process with a filtration step downstream of clarification to improve the suspended solids removal (System B)
- Lime, sulfide polished, filtered (LSPF)—a polishing sulfide precipitation process featuring lime neutralization and clarification to remove the metal hydroxides followed by addition of a soluble sulfide reagent to reduce the metal solubility and a filtration step to remove the precipitated solids (System C)

These process variations were evaluated with 14 actual raw wastewater feed samples obtained from various industrial firms engaged in electroplating and metal finishing. The pilot plant could operate in any of the five modes and could process 0.034 gal/min (130 ml/min) of wastewater in a continuous treatment sequence. Samples were pretreated as required for chromium reduction and cyanide oxidation. Attempts were not made to reduce hexavalent chromium with sulfide reagent.

In the sulfide process variations, the soluble sulfide reagent addition was controlled automatically by a specific-ion sulfide reference electrode pair to maintain a preselected potential of −550 mV with respect to the reference electrode. The value of −550 mV corresponds to about 0.5 mg/l of free sulfide, which was selected as the control point because at that concentration:

- The curve of electrical potential versus sulfide concentration has its maximum gradient.
- The wastewater solution has no detectable sulfide odor.

The study reported that the dependability of the sulfide specific-ion electrode was excellent during the 6-month test period.

Test Results. Results of five of the pilot tests are presented in Tables 2 and 3. Table 2 lists the characteristics of the wastewater before treatment, the volume of sludge generated, and the amount of reagents consumed in the treatment. Table 3 compares the amount of metal per liter of raw feed before treatment and wastewater after treatment using the five process variations.

Pilot Test 1 simulated treatment of a wastewater containing a high concentration of chromium and moderate levels of copper and zinc. As can be seen from the effluent quality of the LO-CF process, the hydroxide solubilities of the metals in this wastewater were quite low and use of a sulfide reagent to achieve lower metal solubilities was not required. The significant reduction in the chromium concentration across the filter can be seen by comparing the effluent quality of the LO-C and LO-CF processes. This situation points out how poor solids removal can have significant adverse effects on an otherwise effective metal precipitation treatment system.

Pilot Tests 2 and 3 were performed with wastewaters that were not effectively treated by hydroxide precipitation. In these tests, significantly improved effluent quality was achieved by sulfide precipitation treatment. In Pilot Test 2, the effluent produced by the LO-CF process contained relatively high levels of zinc and copper, 2.3 and 0.8 mg/l, respectively. Treatment with a soluble sulfide compound considerably reduced the effluent concentration of these metals. In Pilot Test 3, soluble sulfide treatment of wastewater with a high zinc concentration was significantly more effective than hydroxide precipitation.

Tests also were conducted on wastewaters containing an assortment of heavy metals at relatively high concentrations. The results of Pilot Tests 4 and 5 (shown in Table 3) indicate that low levels of all metal pollutants could not be achieved by treatment of these particular wastewaters with either hydroxide or sulfide precipitation. In Pilot Test 4, sulfide precipitation removed the cadmium, copper, and zinc to considerably lower levels than the hydroxide precipitation process, but both processes had a high residual nickel concentration in the effluent. A similar situation occurred with nickel in Pilot Test 5.

Table 3.

SOURCE: *Sulfide Precipitation of Heavy Metals*, EPA Grant 5805413, in preparation.

The data on effluent quality from this study suggest the following general conclusions about the treatment of wastewater with either hydroxide or sulfide precipitation for removal of heavy metals:

- In most cases, metal removal can be improved by precipitating metals as sulfides rather than as hydroxides.
- Some wastewaters can be effectively treated to low residual concentrations of all metals present by either hydroxide or sulfide precipitation processes; some wastewaters cannot be effectively treated by either hydroxide or sulfide precipitation.
- Consistent removal of metals to effluent concentrations of less than 1 mg/l requires filtration to remove residual suspended solids. Because fine particles (which include precipitated metals) are only minimally different in density from water, they cannot be effectively separated by clarification and therefore contribute to the effluent metal concentration.

Another significant finding of the study is the quantity of sulfide reagent consumed in precipitating the metals as sulfides. In the LWS processes, the bulk of the test runs consumed between 1.0 and 2.5 times the stoichiometric sulfide reagent demand based on the total mass of metals that form sulfides in the wastewater. This reagent demand factor supports the belief that all metals are precipitated as sulfides and that any metals initially precipitated as hydroxides are converted to metal sulfides.

In the LSPF process, the metals precipitated as hydroxides are separated by clarification before addition of the sulfide reagent. The sulfide reagent demand for most of the LSPF process tests ranged from 2 to 6 times the stoichiometric sulfide reagent demand. The stoichiometric demand in this case can be calculated from the concentration of metals in the LO-C effluent. The study contained no conclusions as to the cause of the significantly higher sulfide reagent demand relative to the stoichiometric requirements.

SSP System Description and Performance

Although only a few plants currently treat their wastewater with SSP, this process has proved effective for precipitation of many of the metals typically encountered in electroplating wastewater. At present, however, no commercial units are demonstrating the treatment of heavy metals at the high concentrations typical of metal finishing industry wastewater. The primary application of SSP has been for waste streams containing low concentrations of metals and complexing agents, which interfere with effective metal removal by hydroxide precipitation.

Figure 9a is a schematic of a continuous SSP system used to treat a heavy metal waste stream discharged from a large mechanical equipment manufacturer. Part of the wastewater results from electroplating and surface finishing operations. The wastewater pH is adjusted to 7.5 in the first-stage neutralizer and is maintained at approximately 8.5 in the second-stage neutralizer. If the pH falls below 7 in the first stage, a low-pH alarm sounds and the pump feeding the second-stage neutralizer is shut off. Consequently, a surge volume is required in the system to store the wastewater until the pH returns to the control set-point. Sodium hydrosulfide is added in the second-stage neutralizer at a rate set to maintain a dosage of 5 to 10 mg of free sulfide per liter of wastewater. Automatic controls are not used to adjust sulfide reagent feed rate to account for changes in demand. The required sulfide reagent addition rate is determined by periodic testing.

The system shown in Figure 9a uses a separate hexavalent chromium reduction system, although the free sulfide can potentially accomplish the reduction. This approach was not evaluated because performing chromium reduction in the second-stage neutralizer would increase sulfide reagent demand to approximately 35 to 50 mg/l of feed (based on consumption equal to twice the stoichiometric reagent demand) and would make sulfide reagent demand considerably more variable. Without an automatic sulfide reagent addition system to match supply with demand, the increased variability in reagent demand would reduce the reliability of the treatment system. The existing chromium reduction unit, which uses sodium bisulfite ($NaHSO_3$) as the reducing agent, reduced the hexavalent chromium to the required level. Therefore, sulfide precipitation was used only to achieve the superior metal removal required by the discharge permit.

The reduction in the metal solubility achieved by adding NaHS to this plant's wastewater is shown in Table 4. The data indicate that the metal solubility decreases as the sulfide reagent dosage increases.

Figure 9.

SSP Treatment Systems: (a) Continuous and (b) Batch

Table 4.

Sulfide Precipitation of Cadmium, Zinc, and Mercury

Metal (mg/l)	Raw waste	Supernatant[a]			
		Hydroxide solubility at pH of 8.5	Sulfide addition (mg/l)		
			1	5	10
Cadmium	2.1	2.0	1.6	0.39	0.08
Zinc	3.0	2.25	1.8	1.5	1.1
Mercury	0.006	0.0027	0.0013	0.001	0.0008

[a]Polyelectrolyte dose = 1 mg/l; settling time of 2 hours.

Note.—Stoichiometric sulfide requirement to precipitate mixture given is 2.1 mg/l of sulfide based on raw waste composition.

Table 4 also shows the solubilities of the metal hydroxides after pH adjustment to 8.5. Effective metal removal is achieved by this treatment system with a sulfide reagent in the sulfide dosage range of 5 to 10 mg/l.

Figure 9b shows a commercially operated batch wastewater treatment system using a soluble sulfide reagent. The system includes two batch treatment tanks, each sized to hold 1 day's wastewater flow. The sequence of treatment follows:

1. The pH of the full, off-stream tank is raised automatically to a value of 11 by the addition of hydrated lime.
2. Depending on the volume of wastewater in the tank, a quantity of NaHS is metered into the tank.
3. The tank is agitated for approximately 30 minutes and a sample is taken, filtered, and analyzed for the metal that is characteristically most difficult to remove.
4. If the metal concentration is low enough, the contents of the tank are pumped through a diatomaceous earth precoat pressure filter and, after final pH polishing (to 8), are discharged. If the reference metal level is not low enough, additional NaHS is added and Steps 3 and 4 are repeated.

Table 5.

Removal of Complexed Copper and Other Metals From Electroplating Wastewater

Metal (mg/l)	Untreated wastewater	Filtrate
Copper	17	0.4
Nickel	0.3	<0.2
Lead	1.85	<0.2
Zinc	0.86	0.4
Tin	4.29	<1.0

Note.—Batch treatment sequence: lime added to pH of 11; NaHS added to equivalent sulfide ion concentration of 20 mg/l (stoichiometric requirement = 10 mg/l); filtered through diatomaceous earth filter; final pH adjustment to 8 before discharge.

The performance of the batch system in reducing the level of total metals in the wastewater discharge is presented in Table 5. As shown, the pH of the wastewater is raised to 11 before NaHS is added. Experimentally, it was found that the sulfide addition would reduce the dissolved metal concentration to equally low levels at a pH of 8.5. Removal of fluorides present in the plant's wastewater, however, required elevating the pH to 11.

The continuous and batch SSP systems described in this section are located in segregated waste treatment areas. Despite careful control of the wastewater pH and sulfide addition rate, the H_2S odor in the area was a nuisance. To reduce the ambient level of H_2S, the open-top treatment tanks where the sulfide reagent is added to the wastewater were modified into closed-top, vacuum-evacuated tanks. In the batch system shown in Figure 9b, the final pH adjustment tank contributed to the odor problem and was modified similarly. The exhaust from these tanks, which contains a low level of H_2S, is vented outdoors. These changes, plus rigid control of pH and sulfide dosage levels, have resulted in an almost undetectable H_2S odor in the waste treatment area.

SSP Polishing Treatment System

Sulfide reagent demand for the SSP treatment system shown in Figure 9a is a function of the total metal concentration of the raw wastewater. Sufficient reagent must be supplied to convert all entering metals to metal sulfides. In treating wastewater containing high metal loadings, significant sulfide reagent cost savings can be realized by using SSP to polish the effluent after a conventional pH adjustment/clarification treatment sequence (Figure 10). The LSPF process evaluated in the pilot studies discussed earlier simulated the use of SSP as a polishing system. There are no commercially operated SSP polishing systems currently in operation.

In addition to reducing sulfide reagent consumption, using sulfide precipitation as a polishing system will reduce the variability of reagent demand. The reagent demand for the polishing system will be a function of wastewater flow and the concentration of metals in the overflow from the first-stage clarifier. The metal concentration in the wastewater at this point

Figure 10.

SSP Polishing System

should not be subject to the wide variability that often characterizes the raw wastewater feed metal concentration. Without an automatic reagent addition control loop, dosing the wastewater with a predetermined amount of sulfide reagent would be considerably more reliable in a polishing treatment application.

The plant operating the treatment system shown in Figure 9a evaluated the use of SSP as a polishing treatment to reduce the variability of sulfide reagent demand. It was found that clarifying the wastewater before adding the sulfide reagent resulted in the formation of poor-settling particles that were difficult to remove from the wastewater. The current treatment sequence, in which the sulfide reagent is added in the second-stage neutralizer, removes precipitated metal more effectively. It was concluded that the presence of the precipitated metal hydroxides and lime solids in the wastewater entering the second-stage neutralizer provided nucleation sites, which promoted the coagulation of the precipitated metal sulfides.

An SSP pilot study reports success in forming metal sulfide particles that were easily removed from the wastewater despite precipitation in a solution lacking nucleation sites. The researchers found that conditioning the colloidal metal sulfide precipitants with a cationic coagulant to increase the particle size and then adding an anionic flocculant to link the particles produced large, fast-settling particles when flocculated. In the pilot study discussed previously, the sulfide polishing process precipitated metals as sulfides after the wastewater had been clarified to remove suspended solids. The study indicated that the metal sulfide solids were removed effectively by filtration.

The additional equipment requirements of a polishing treatment system include a second mixing tank to add the sulfide reagent and a second solids separation unit (using either a clarifier or a filter) installed downstream of the metal hydroxide clarification step. A second polyelectrolyte addition system also may be required to enhance the efficiency of the metal sulfide solids separation step.

Hydroxide System Modifications for SSP

Augmenting a hydroxide precipitation wastewater treatment system

Figure 11.

Conversion of Hydroxide Treatment System To Use SSP: (a) Hydroxide Precipitation System, (b) SSP System, and (c) SSP System With Automatic Control of Sulfide Residual

with SSP to achieve a lower level of metals in the effluent can be a cost-effective means of achieving compliance. The cost of using soluble sulfide treatment will be significantly affected by the reliability and dependability of using the specific-ion sulfide reference electrode to control the sulfide reagent addition. If the residual sulfide concentration can be maintained consistently at a level of 0.3 to 0.5 mg/l in the wastewater, it should not be necessary to modify existing treatment tanks to eliminate sulfide odor in the work area. Because the reliability of the control system has not been established, two alternative approaches emerge for converting a hydroxide system to use SSP.

With no automatic control of the level of residual sulfide in the wastewater, converting the conventional hydroxide precipitation system (Figure 11a) to an SSP system (Figure 11b) requires

several process modifications. The modifications, which are discussed in the following paragraphs, include:

- NaHS reagent feed tank and feed pump
- Second-stage neutralizer/soluble sulfide treatment tank
- Clarifier enclosure and vacuum evacuation
- Control system
- Sand filter or other polishing filtration unit
- Aeration system

The NaHS feed tank should have a closed top with a vent connecting to an exhaust system. In installations where venting any odor is considered a public nuisance, the vent can be connected to a scrubber system. Using a scrubber eliminates the discharge of any odor, whereas simply venting outdoors eliminates any hazard to the worker during reagent preparation. The feed pump should be a positive displacement pump with a variable stroke to facilitate the metering of reagent into the system.

The second-stage neutralizer/soluble sulfide treatment tank is used for adding the sulfide reagent to the wastewater. The tank also provides improved pH control to ensure that the sulfide reagent does not come into contact with acidic wastewater. The tank contents should be agitated. The tank should be sized to provide a minimum retention time of 20 min, and it should be equipped with a pH control loop and alkali neutralizing reagent feed system. To minimize any H_2S odor associated with the treatment, the tank should be totally enclosed and vacuum evacuated.

To convert the conventional hydroxide precipitation system to an SSP system, it is also necessary to totally enclose and vacuum evacuate the clarifier.

A control system is needed to avoid mixing of the sulfide reagent with low-pH wastewater. An instrumentation loop that interrupts the wastewater feed to the sulfide treatment tank if the pH of this stream falls below set-point is one way of minimizing the potential hazard. Low-pH conditions also should sound an alarm and interrupt the sulfide feed to the system. This type of control will result in the need for surge volume upstream of the sulfide treatment tank to store the volume buildup until the pH is brought back above the set-point.

A sand filter or other polishing filtration unit that removes suspended solids in the clarifier overflow to very low levels is recommended for any treatment system that must achieve very low levels of metals in the effluent. The significance of reducing the solubility of a metal pollutant by means of sulfide precipitation will be lost unless the level of suspended solids, which include insoluble metals, is also controlled at a low level.

An aeration system may be needed to oxidize residual sulfide before wastewater discharge. If wastewater is discharged into a sewer system, precautions must be taken to ensure that the discharge does not contain high levels of sulfide. Discharge of wastewater containing significant quantities of sulfide could be hazardous to individuals working in a poorly vented sewer system. No specific limit exists for direct discharge of sulfide, but its presence contributes to the biochemical oxygen demand (BOD) of the wastewater. The easily oxidized sulfide compounds can be treated in an air-sparged tank with a retention time of approximately 30 min. If indoors, this tank also should be totally enclosed and vacuum evacuated.

For a process using automatic control of the sulfide reagent addition (Figure 11c), the required modifications to convert the hydroxide system to an SSP system would include the following:

- NaHS reagent feed tank and feed pump—identical to the tank and pump required for the previous case, except the feed pump is actuated by a signal from the sulfide reagent control system to maintain a constant residual sulfide concentration in the wastewater
- Second-stage neutralizer/soluble sulfide treatment tank—for addition of the sulfide reagent to the wastewater, but in this case the residual free sulfide ion concentration is maintained at a level below 0.5 ppm by means of a sulfide ion control loop
- Control system to avoid mixing of the sulfide reagent with low-pH wastewater
- Sand filter

The second-stage neutralizer/sulfide treatment tank and the downstream process tanks will not need to be enclosed and vacuum evacuated if careful control of pH (between 8 and 9.5) and sulfide ion concentration is maintained. Control of sulfide ion concentration also should eliminate the need to aerate the wastewater before discharge. The other elements of the sulfide system shown in Figure 11—first-stage pH adjustment, polyelectrolyte conditioning, and clarification—are common to hydroxide precipitation systems.

For batch treatment SSP systems, a two-tank system for alternately collecting and treating the wastewater would be required. The treatment sequence for a batch system was presented earlier. If the residual level of sulfide cannot be controlled, aeration of the wastewater after chemical treatment may be required in addition to enclosing and vacuum evacuating

the tanks during treatment. The wastewater could be aerated in the treatment tank before flocculation (if required) and solid/liquid separation.

Retrofitting a hydroxide system to use soluble sulfide polishing would require a mixing tank to add the sulfide reagent to the wastewater downstream of the existing clarifier and a second solids separation unit. Because the solids generation rate in the soluble sulfide polishing step should be low, a sand or mixed-media filter should be suitable for removing the suspended solids from the wastewater before discharge.

Polyelectrolyte conditioning and flocculation may be required between the sulfide reagent addition tank and the solids removal filter. Without instrumentation for reliable control of the residual sulfide concentration, the sulfide reagent mixing tank and downstream equipment would need to be enclosed and ventilated, and aeration of the effluent might be required.

Table 6.

Equipment Cost Factors for SSP Treatment Systems

Equipment component	Installed cost ($1,000),[a] by wastewater flow rate (gal/min)		
	30	60	90
Sodium hydrosulfide feed tank and metering pump	3.3	3.3	3.3
Automatic sulfide reagent addition control	3.5	3.5	3.5
Low-pH prevention control loop	1.5-2.0	1.5-2.0	1.5-2.0
Second-stage pH adjustment and sulfide reagent mixing tank:			
Open top	18	22	24
Totally enclosed and vented	23	28	30
Suspended solids polishing filter	24	33	41
Aerator	4	7	9

[a]March 1979 cost basis. Installed costs of different components are presented. Engineering and design costs, site preparation, and equipment freight charges are not included.

SSP Cost Estimating

Improving the performance of a hydroxide precipitation system through the use of SSP will require investment capital to modify the treatment system and will increase the cost to operate the system.

There is some uncertainty in predicting the extent of the modifications needed to convert a hydroxide system to use SSP. Demonstration of the reliability of automatic control of the sulfide reagent feed is needed to eliminate this uncertainty. Table 6 presents the costs (including hardware and installation) of the different equipment components that may be required:

- NaHS feed tank and metering pump
- Automatic control of sulfide reagent addition
- Low-pH prevention control loop
- Mixing tank
- Suspended solids polishing filter
- Aerator

The cost for a sodium hydrosulfide feed tank is based on a 400-gal (1,514-l), closed-top, carbon-steel tank that has a removable lid, exhaust vent, and appropriate nozzles. The diaphragm metering pump is rated to deliver 0 to 20 gal/h (0 to 76 l/h).

A specific-ion sulfide reference electrode pair automatically controls the sulfide reagent feed pump. A control loop prevents low-pH conditions in the sulfide treatment tank by automatically shutting down the wastewater feed pump and sulfide reagent feed pump if the wastewater pH falls below the control set-point. The cost presented assumes the prior existence of a pH probe and a surge volume to hold the diverted flow.

Second-stage pH adjustment and sulfide reagent addition occur in an agitated tank sized for 20-min retention of wastewater. Costs are given for both an open-top and a totally enclosed and vented tank.

The suspended solids polishing filter costs presented are for dual mixed-media filters, skid mounted and sized so that one filter can process the maximum flow during backwash. The unit is equipped with a blower for low pressure air scouring, a backwash storage tank, and a pump to bleed the wash back into the treatment system.

The aerator cost is based on an enclosed, vacuum-evacuated tank sized for 30-min retention of wastewater and equipped with an air sparger.

Higher operating costs—for operating labor and treatment reagents—will result from incorporating SSP into an existing treatment system. Additional operating labor will be required to prepare sulfide reagent and to maintain and operate the additional equipment components. Additional expense will result from consumption of sulfide reagent. The consumption rate will depend on the volume of wastewater treated and the

[a]Based on NaHS (72% flake) at $370/ton.

[b]Total treatment at 2 times the stoichiometric reagent demand.

[c]Polishing treatment at 4 times the stoichiometric reagent demand and a total metal hydroxide solubility of 10 ppm.

[d]Includes all metals that form sulfides, based on metal with molecular weight of 62.5 (average of Ni, Cu, and Zn).

Figure 12.

Soluble Sulfide Reagent Cost

required dosage. The dosage per volume of wastewater treated will be a function of the wastewater metal concentration. Figure 12 presents the sulfide reagent cost per 1,000 gal (3,800 l) of wastewater treated as a function of metal concentration for an SSP system used to treat the total metal load as well as for polishing treatment.

Sludge generation rates will increase with the use of SSP compared with a conventional hydroxide treatment system because of improved metal removal, but the increase should be insignificant. For example, precipitating an additional 5 ppm of dissolved metals from a waste stream will increase the clarifier underflow rate by less than 1 gal of sludge per 1,000 gal of wastewater treated, based on an underflow concentration of 1 percent solids by weight. Also, the dewatering properties of sulfide sludges are believed to be superior to those of hydroxide sludges, although limited information is available to support this view.

If the pH of the neutralized wastewater is increased to minimize odor, more alkali will be consumed, causing an increase in cost. The increased cost of alkali should not be significant except for high-volume treatment systems. Use of a pH above 10 would necessitate a final adjustment to lower the pH to the acceptable discharge range.

Insoluble Sulfide Precipitation

A commercially available ISP wastewater treatment system was developed to provide a treatment process that offers the superior metal removal of sulfide precipitation systems without the unpleasant H_2S odor often associated with soluble sulfide systems. Since the first commercial demonstration of the process in 1978, additional installations have become operational. The process is patented, and its use requires payment of a licensing fee to the patent holder. This section describes the process, presents performance data on three currently operating systems, and evaluates use of the process for treatment of electroplating wastewaters.

Process Description

Process Equipment Components. A hydroxide neutralization/ISP treatment system for control of pH and precipitation of heavy metals is depicted in Figure 13. In this system, the hexavalent chromium is reduced to its trivalent state by the sulfide and ferrous ions present in the mixer/clarifier, thus eliminating the need for a separate chromium reduction unit. With the exception of chromium and iron, all other heavy metals in the wastewater precipitate as sulfides. The key elements of the system are:

- pH control
- Mixer/clarifier
- Reagent addition to mixer/clarifier
- FeS feed rate control
- Sand filter

Effective metal removal by sulfide or hydroxide precipitation requires that the pH of the wastewater be controlled within the neutral to slightly alkaline range. Although the dependence of metal solubility on pH is not critical for sulfide precipitation systems, it still affects metal removal (see Figure 3). It is more important to eliminate the danger of the FeS slurry coming into contact with acidic wastewater; FeS is soluble in acidic solutions, and mixing it with low-pH wastewater would result in the emission of toxic H_2S fumes in the work area. The risk is minimized by installing a recycle control on the feed to the mixer/clarifier. If the pH of the feed stream drops below 7, valves automatically reroute the feed back to the second-stage neutralizer. For this reason, a surge volume, shown as V_s in Figure 13, is required to store the accumulated wastewater until the control set-point is reestablished.

The mixer/clarifier shown in Figure 13 serves two purposes. First, it provides the solid/liquid contact volume between the wastewater and the FeS slurry necessary to maintain the wastewater sulfide-ion concentration at its saturation point. As illustrated in Figure 6, both mixing time and sludge blanket density in the solid/liquid contact zone affect metal removal. Second, it clarifies the effluent of suspended solids.

To achieve low concentrations of dissolved metals, which are characteristic of metal sulfides, the liquid residence time in the solid/liquid contact zone of the mixer/clarifier must be sufficient for the metal precipitation reaction to reach completion. Proper agitation in the contact zone will enhance the degree of reaction completion achieved as well as promote particle growth of the precipitated metal sulfides. The formation of large, rapid-settling particles facilitates removal of the solids by clarification.

Reagent addition to the mixer/clarifier is controlled by a flow-measuring device that monitors the feed to the mixer/clarifier and sends a signal to a counter, which computes the cumulative flow. The additions of fresh FeS and polymer are controlled to provide a set quantity of each when

Figure 13.

Sulfex™ ISP Treatment System

Figure 14.

Impact of Averaging Tank Volume on Reagent Demand Variability

the counter records a set volumetric throughput. The dosage rate is determined for both reagents by performing a series of jar tests. A sample is taken from the second-stage neutralizer and tested to determine the required addition of FeS.

Jar tests are conducted on approximately four samples to determine the lowest FeS dosage that provides optimum metal removal. Because polyelectrolyte demand should be proportional to the demand for FeS, it is fed at a constant ratio of the demand for FeS. Jar tests normally are conducted once or twice per shift to determine the required addition rate.

The FeS feed rate control loop automatically adds a preset amount of reagent each time an increment of wastewater enters the mixer/clarifier. The amount of reagent added is set manually based on the results of the jar tests. The inability to adjust the FeS reagent dosage automatically in response to changes in reagent demand complicates operation of ISP treatment systems. To compensate for the lack of automatic control, two features must be considered in design of the system:

- FeS reagent demand averaging
- Maintaining an inventory of unreacted FeS in the mixer/clarifier

Reagent demand averaging requires the elimination of sharp deviations in wastewater flow rate and pollutant concentration entering the treatment system. Flow variability normally is eliminated by providing a surge volume upstream of the treatment process and treating the wastewater at a constant average rate. The variability of pollutant concentration can be reduced by use of an averaging tank—an agitated tank that stores and blends the treatment system feed before processing. The impact of averaging tank volume and retention time on reagent demand variability is presented graphically in Figure 14. As shown, with 1 hour of retention time in upstream process tanks, the

variability of the mixer/clarifier (blended feed) reagent demand is equal to 54 percent of the plant feed reagent demand variability; with 4-hour retention time in upstream process tanks, the mixer/clarifier reagent demand variability is reduced to 15 percent of the plant feed variability. The graph presents an idealized situation of reagent demand fluctuating around a constant average demand. In actual practice, however, the deviations may be long term and may not average out to a constant demand rate. The relationship between retention time in upstream blending tanks and demand fluctuations is a key to operating any treatment process that does not adjust reagent supply to changes in demand automatically.

Maintaining an inventory of unreacted FeS in the mixer/clarifier is needed to provide the sulfide reagent when reagent demand exceeds supply. Because demand fluctuations are inevitable, an inventory of reagent is essential to consistently achieve maximum removal of metals. The quantity of FeS stored in the mixer/clarifier is proportional to the quantity of solids maintained in the unit and to the concentration of FeS in those solids.

A sand filter is included in the system to ensure that the wastewater discharge contains a minimum concentration of suspended solids. To meet strict metal discharge requirements, the level of dissolved and insoluble metals in the effluent discharge must be reduced to a minimum. For both sulfide and hydroxide precipitation systems, a sand filter ensures that upsets in the treatment system causing turbidity in the clarifier overflow will not jeopardize effluent quality.

FeS Reagent Consumption. As shown in Figure 6, precipitation of dissolved metals to the low solubility level characteristic of metal sulfides normally requires 2 to 4 times the stoichiometric amount of FeS. The ratio of the amount of reagent added to the stoichiometric demand establishes the equilibrium concentration of FeS in the sludge blanket solids. The FeS added in excess of the stoichiometric demand provides the inventory of unreacted reagent that is consumed when reagent demand exceeds supply.

The concentration of FeS in the sludge blanket as a function of the ratio of reagent addition to stoichiometric reagent demand is shown in Figure 15. The quantity of reagent consumed as a function of this ratio also is shown. Because the underflow rate is set to balance the solids loading rate, the concentration of FeS in the sludge blanket also determines the amount lost in the sludge underflow.

By defining the volume of the solid/liquid contact zone and the density of the sludge blanket in this zone, the amount of FeS stored can be approximated. The larger the quantity of unreacted FeS maintained in the blanket, the greater the ability of the system to compensate automatically for increases in reagent demand. The FeS supply can be increased by:

- Increasing the FeS reagent feed rate
- Designing larger solid/liquid contact volume into the system
- Maintaining the maximum sludge blanket solids concentration in the solid/liquid contact volume that is compatible with good clarification in the settling zone of the mixer/clarifier

The first two methods of increasing the FeS inventory have economic penalties: reagent cost and sludge volume rise as dosage is increased, and the initial cost and space requirements increase as larger mixing volume is designed into the system. Therefore, maintaining a dense sludge blanket in the mixing zone is the most efficient way to achieve good reagent use and to provide the inventory of FeS needed for reagent demand increases. In practice, this requires monitoring the blanket level and adjusting the sludge drawoff rate to match the solids accumulation rate in the system.

Operating Procedure. The ISP system shown in Figure 13 required a full-time operator during one shift and approximately 2 to 4 hours of operator attention during other shifts. Operator duties are as follows:

- Once each shift, a sample of mixer/clarifier feed is removed from the second-stage neutralizer for jar testing to determine the required FeS addition rate.
- Based on the jar test results, the FeS and polyelectrolyte addition control system is set to feed the needed quantity of reagents each time a set feed increment has entered the mixer/clarifier.
- The timer that controls the sludge blowdown is adjusted to reflect any change in the solids loading rate. (This relates to the jar test performed in the first step.)
- The level of solids in the mixer/clarifier is monitored periodically (normally every 1 or 2 hours) by performing a settling test on samples removed from the mixing zone of the mixer/clarifier. The sludge blowdown rate is adjusted to maintain the maximum solids concentration in the

Figure 15.

Sludge Blanket FeS Concentration and Associated Reagent Demand

mixing zone that is compatible with low levels of turbidity in the clarified effluent.

Other operator duties generally required for operation of this system and most treatment systems include:

- Preparation of treatment reagents—in this case, reagents include lime slurry, Sulfex™ reagent (Figure 16), and polyelectrolyte
- Operation of sludge dewatering filter
- Periodic back-flush cleaning of the sand filter
- Periodic calibration of pH probes
- Collection of samples required for discharge permit
- Regularly scheduled lubrication of system elements

Figure 16.

FeS Feed System

ISP Polishing Treatment System

The FeS reagent demand for the system shown in Figure 13 is a function of the total metal load entering the mixer/clarifier. Sufficient FeS must be added not only to precipitate the dissolved metals but also to convert the precipitated metal hydroxides to metal sulfides. For treatment systems with a high mass flow of metals, FeS consumption will be high and considerable waste solids (a combination of metal sulfides, metal hydroxides, and unreacted FeS) will be generated. For these applications, the reduction in reagent consumption and solid waste disposal charges may justify using ISP to polish the clarified overflow after a conventional hydroxide precipitation/clarification treatment sequence (Figure 17).

In this polishing system, the FeS demand is based on the metals contained in first clarifier overflow. If hexavalent chromium is present in the wastewater, it will be reduced in the second-stage mixer/clarifier and precipitated along with the dissolved metals. Two advantages of this approach, compared with the system shown in Figure 13, are reduced FeS reagent demand and reduced sludge generation, which is a function of metal loading and reagent consumption. Another advantage is that the concentration of metals in the first-stage clarifier overflow will not be subject to the wide variation that often characterizes the wastewater feed metal concentration. The metal hydroxide equilibrium solubility will determine the concentration of dissolved metals in the overflow; this concentration will establish reagent demand. Again, because reagent supply is not adjusted automatically for changes in demand, this feature increases reliability. The concentration of hexavalent chromium, which is unaffected by the hydroxide treatment, will still be subject to variation, but the variability should be reduced because of the larger volume of upstream process tanks in a polishing treatment system.

Figure 17.

ISP Polishing System

Identification of the optimum system—polishing sulfide precipitation or treatment of the total metal load—requires determining whether the operating cost savings of the polishing system offset the additional cost of a second mixer/clarifier and polyelectrolyte feeder.

Table 7.

Plant A Discharge Permit Requirements

Item	Discharge limits[a]			
	Mass (lb/d)		Concentration (ppm)	
	Average[b]	Maximum[c]	Average[b]	Maximum[c]

ISP System Performance

Three plants currently use the Sulfex™ system to remove heavy metals from wastewater discharge. All three systems were placed in plating shops where no wastewater treatment systems existed. Two of the plants (Plants A and B) treat the total metal load with FeS, whereas the third (Plant C) employs ISP as a polishing step after hydroxide precipitation/clarification.

Plant A performs copper, nickel, and chromium plating (both electroplating and electroless plating) of plastic components. The heavy metals in the wastewater are complexed with a variety of chelating agents. During the pilot evaluation, it was apparent that hydroxide precipitation would not remove the metals to the levels required in the discharge permit (Table 7). After a pilot evaluation showed that ISP could achieve the required discharge limitations, the firm hired a vendor to design a treatment system using this technology. The vendor guaranteed that the system would meet all discharge regulations.

Figure 18.

Plant A's Performance in Removing Chromium

The system was designed to treat 40 gal/min (151 l/min) of wastewater and is essentially identical to the system shown in Figure 13. The performance of the system in removing copper, nickel, total chromium, and hexavalent chromium (Cr^{+6}) during a 60-hour test period is shown in Figures 18 and 19. Figure 20 shows the corresponding sample point locations.

The performance in chromium removal shows a deviation from normal removal efficiency between hours 16 and 28 that corresponds to an increase in the level of hexavalent chromium in the mixer/clarifier feed during hours 8 through 28. By comparing the stoichiometric FeS demand with the quantity supplied and the associated mixer/clarifier removal efficiency (Figure 21), it is obvious that the FeS feed was not increased sufficiently to compensate for the increased demand. Consequently, the level of unreacted FeS in the sludge blanket was gradually depleted, and at hour 16 insufficient FeS was present in the blanket to achieve the normal high level of removal. This condition persisted until hour 28. The FeS stored in the sludge blanket maintained the high removal efficiency between hours 8 and 16, despite a low FeS reagent supply/demand ratio.

Figure 19.

Plant A's Performance in Removing Nickel and Copper

Figure 21 shows that optimum removal efficiency for the chromium is achieved with an FeS dosage of approximately 3 times the stoichiometric demand. Stoichiometric demand was determined by laboratory analysis of mixer/clarifier feed samples. The removal efficiencies for nickel and copper were relatively constant and showed no discernible trends over the dosage ratios encountered during the test period.

Based on an FeS dosage rate of 3 times the stoichiometric demand and the observed consumption of other treatment reagents, the cost of treatment chemicals and sludge generation factors for the ISP system at this facility are shown in Table 8.

Plant B manufactures carburetors for the automotive industry. Wastewater from the metal finishing portion of the process contains varying quantities of chromium (hexavalent and trivalent), zinc, and iron in solution with phosphates, organic chelating agents, and assorted chemicals used in the process baths. The wastewater is treated in a neutralization/ISP/clarification treatment sequence similar to that shown in Figure 13. Then it is mixed with the remainder of the wastewater from the plant and is discharged to the city wastewater treatment system.

Figure 20.

Sample Points

Anionic and cationic polymer feed systems

The wastewater flow rate to the system averaged 20 gal/min (76 l/min). The performance of the system during a 2-day test in removing chromium (total and hexavalent), zinc, and iron from the wastewater is shown in Figures 22 and 23. The same sample location designation used in Figure 20 applies. Figure 24 defines the ratio of FeS supply to stoichiometric demand for the same test period. The ratio varied from 3 to 5 times the stoichiometric demand during the test period. The quality of the effluent, which contained lower pollutant levels than those specified in both local and State guidelines, showed no discernible trends within this range of reagent supply/demand ratios.

The cost of treatment chemicals and the sludge generation factors for the ISP system at this facility are shown in Table 8. Chemical costs were approximately $1.77/1,000 gal of wastewater treated.

Plant C uses the ISP process to polish the clarified overflow from a conventional hydroxide precipitation/clarification treatment sequence. The system treats approximately 15 to 18 gal/min (57 to 68 l/min) of wastewater from a programed, barrel-dip, zinc-phosphatizing plating line. The system is similar to the one shown in Figure 17; it has a second mixer/clarifier and polymer feed system, installed after the second-stage neutralizer, to remove the precipitated metal hydroxides and phosphates. Dual polyelectrolyte feed systems are needed because an anionic polymer is used in the hydroxide removal clarifier and a cationic polymer is used to enhance the settling of the precipitated metal sulfides. The sludge production and FeS consumption are reduced considerably compared with a system

[e]Without the presence of phosphates, treatment cost equals $0.81/1,000 gal, solids generation equals 6.4 lb/1,000 gal.

Note —1979 cost basis, NA = not applicable.

treating the total metal load with sulfide precipitation. Less than 5 percent of the waste solids removed from the system are attributed to the sulfide precipitation step.

Table 8 presents the chemical consumption and sludge generation rates for Plant C. Treatment of the phosphates in the wastewater accounts for a large percentage of the treatment cost, and the phosphate solids constitute the bulk of the sludge generated. The chemical cost associated with removal of the heavy metals contained in the wastewater was estimated at $0.81/1,000 gal. Without the presence of phosphates, the solids generation rate would equal 6.4 lb/1,000 gal (0.76 kg/m^3) of wastewater.

Table 9 presents the pollutant concentrations in Plant C's raw waste and effluent discharge and shows the effluent quality required by the discharge permit.

In this polishing application, FeS is fed into the second-stage mixer/clarifier to yield a concentration of approximately 40 ppm in the wastewater. The dosage rates for the insoluble solids systems treating the total metal load for Plants A and B are approximately 640 ppm and 430 ppm, respectively.

Note: The plant operates two shifts per day, from 8:00 to wastewater flow between hours 16 and 24.

Figure 27

Plant B's Performance in Removing Iron and Zinc

Hydroxide System Modifications for ISP

The metal removal efficiency of a hydroxide precipitation system can be improved by incorporating ISP into the system. Sulfide precipitation can be used either to convert the metals to metal sulfides before the clarifier or as a polishing system to precipitate dissolved metals from wastewater after the insoluble metal hydroxides have been removed by clarification.

Equipment Requirements. The key component of an ISP system is the solid/liquid contact chamber where the wastewater is mixed thoroughly with the insoluble sulfide contained in the sludge blanket. Three design criteria must be addressed in specifying the power of equipment:

- Liquid residence time in the mixing zone
- Sludge blanket volume and density
- Mixing efficiency

Figure 28 is a schematic of the mixer/clarifier designed specifically for this application. In the systems currently using ISP, the unit is sized to provide approximately 1 hour of liquid residence time in the mixing zone. Because the mixing zone volume is equal to the solids retention volume, a large inventory of unreacted FeS can be maintained in the unit. The agitator is designed to maintain a dense, fluidized sludge in the mixing zone. Sample ports are located in the different zones of the unit to check the sludge density. The unit also has a timed sludge drawoff valve that can be set to balance the blowdown to the solids accumulation rate automatically.

Figure 23.

Plant B's Performance in Removing Chromium

Other elements needed to augment a treatment system with ISP include:

- FeS reagent preparation tanks, reagent storage, and feed pumps
- A reagent feed control system that matches reagent dosage to wastewater flow rate
- A control loop to interrupt the wastewater feed during low-pH conditions

In converting a hydroxide system to use sulfide precipitation, the addition of a polishing filtration system to remove residual suspended solids from the clarifier overflow could significantly reduce effluent metal concentrations. Meeting strict effluent metal discharge limits will require an effluent with low levels of both suspended and dissolved metals.

Treatment System Evaluation. The cost advantages of using ISP as a polishing system must be weighed against the higher equipment costs and space requirements of a second clarifier. It might be more cost effective for plants with small metal loadings to incorporate ISP upstream of the existing clarifier and thus avoid the expense of a second clarifier.

Retrofitting a hydroxide treatment system that already has a flocculation zone to enhance the settling properties of the precipitated metals before clarification can be accomplished simply and with minimum investment. Many existing systems include a flocculation chamber either in a separate vessel or as part of the clarifier itself. As shown in Figure 26, sulfide precipitation can be incorporated

Figure 24.

FeS Supplied vs. Stoichiometric Requirement at Plant B

Table 9.

Influent and Effluent Wastewater Characteristics for ISP Polishing System

Item	Wastewater analysis		
	Influent	Effluent	Permit requirements[a]
pH	2.9	8.5	6.0-9.5
Phosphorus (mg/l)	289	0.3	<1.2
Total suspended solids (mg/l)	320	6	<23
Total chromium (mg/l)	8	<0.10	<0.6
Hexavalent chromium (mg/l)	0.07	<0.02	<0.06
Nickel (mg/l)	0.77	<0.1	<0.6
Zinc (mg/l)	24	0.12	<0.6
Iron (mg/l)	127	0.60	<1.2

[a]Monthly average of daily composite samples.

into this type of treatment system by installing:

- An FeS reagent addition system and feed control system to feed FeS into the flocculation chamber in proportion to the volume of wastewater processed
- A sludge recirculation loop (if not already existing) to recycle solids from the clarifier underflow back to the flocculator
- A low-pH feed interrupt control loop to stop the feed to the flocculator if the pH of this stream falls below the set-point

Pilot tests must be performed to determine if the residence time, agitation, and blanket density in the flocculation chamber are conducive to effective metal removal. Figure 6 defined the different variables for evaluation by pilot testing or jar testing. Deficiencies in the flocculator residence time, mixing efficiency, and the like can be tolerated, although they generally result in increased reagent consumption.

An approach for treatment systems that do not have flocculation zones is either to add a flocculator or to replace the existing clarifier with the mixer/clarifier designed for this application (Figure 25). The most reliable approach to using ISP as a polishing system would be to install a mixer/clarifier downstream of the existing clarifier.

Figure 25.

Cross Section of Mixer/Clarifier

ISP Batch Treatment Systems. Batch treatment systems currently are not demonstrated for ISP. As with continuous treatment systems, batch treatment using ISP would require contact between the wastewater and a dense sludge blanket to achieve maximum metal removal. Consequently, a large volume of solids would be needed for each batch, necessitating storage of the settled sludge after batch treatment. Figure 27 shows a possible configuration of an ISP batch treatment system and the associated treatment sequence. The major process components of the system are:

- Two tanks equipped with mechanical agitation
- A precipitation tank
- Reagent storage and feed systems to add the lime (or caustic), FeS, and polymer

The two agitated tanks alternate as the wastewater collection tank and pretreatment tank. Pretreatment is required to neutralize the acidic wastewater before mixing it with the metal sulfide sludge. A precipitation tank is needed to bring the wastewater into contact with the FeS slurry and to provide storage volume for maintaining an inventory of sludge solids in the system. Gentle agitation is required to suspend the sludge solids during mixing and to promote particle growth of the precipitated solids.

ISP Treatment Costs

Operating Costs. The following costs associated with using ISP are in addition to the operating costs of

Figure 26.

Retrofit of a Hydroxide System With Insoluble Sulfide Treatment

a conventional hydroxide precipitation system:

- Reagent costs for FeS and polyelectrolyte
- Labor cost of additional operational duties described earlier
- Disposal cost of any additional solid waste generated
- Licensing fee charged by the patent holder to use the process

Reagent costs for FeS depend on the quantity of metals to be precipitated (or, in the case of hexavalent chromium, the quantity to be reduced chemically) and the ratio of reagent needed for effective removal to the stoichiometric reagent requirement. Figure 28a shows the FeS consumption rates and reagent cost for various metal concentrations in the wastewater and typical ratios of reagent demand to stoichiometric requirement. The wastewater metal concentration is defined as the metals other than iron that will form sulfides. To compute reagent consumption rates, it was assumed that the metals have a "plus 2" valence and a molecular weight equal to the average molecular weight of copper, nickel, and zinc. Although determination of the optimum dosage ratio requires testing, wastewaters with no heavy metal complexing agents generally require 1.5 to 2 times the stoichiometric reagent requirements, whereas wastewaters containing complexed heavy metals will require 3 to 4 times the stoichiometric reagent dosage. Figure 28b presents the FeS reagent demand and cost for wastewater treatment over a range of hexavalent chromium concentrations.

At the three plants currently operating, labor requirements for the ISP systems varied only slightly. Each plant employed a full-time operator for one shift and required 2 to 6 hours of operator attention on other shifts.

*Tanks 1 and 2 alternate in process function.

Note.—Treatment sequence: When Tank 2 is filled to capacity, incoming wastewater is diverted to Tank 1. The pH of the wastewater in Tank 2 is adjusted to 8.5. A sample is removed from Tank 2 and analyzed by jar test procedure to determine required FeS dosage. The wastewater in Tank 2, along with the required amount of FeS and polymer, is charged into Tank 3. The wastewater/sludge mixture in Tank 3 is agitated for 1 hour. Agitation is stopped and the solids are allowed to settle. A sample of the clarified wastewater is analyzed to check water quality. The wastewater in Tank 3 is decanted and discharged. A portion of the settled sludge is discharged to sludge disposal to maintain a constant sludge inventory.

Figure 27.

Batch Wastewater Treatment Using ISP

The ISP systems generate considerably more sludge in treating a volume of wastewater than the conventional hydroxide precipitation scheme. The additional sludge results from precipitation as hydroxides of the ferrous and ferric ions liberated as the sulfide reagent is consumed and from the excess FeS that is used in treatment. Figure 29 compares the solids generation rates for ISP systems with those for treatment systems using hydroxide precipitation for metal removal and sulfur dioxide (SO_2) for chromium reduction. The graph also shows solid waste disposal charges, assuming the sludge is disposed of at 25 percent solids by weight and at a cost of $0.10/gal. For plants with different sludge disposal cost formulas, the disposal cost can be calculated by multiplying the cost indicated in Figure 29 by the ratio of the actual disposal cost to the assumed rate of $0.10/gal.

Owing to the high cost of sludge disposal—normally from $0.05/gal to $0.20/gal—it is cost effective to invest in mechanical dewatering equipment to reduce the sludge volume. At the three plants currently operating, recessed plate filter presses were installed

Figure 28.

FeS Consumption and Cost Factors for: (a) Precipitation of Metals and (b) Hexavalent Chromium Reduction

to dewater the sludge before transport to the disposal site. The presses dewatered the underflow from less than 1 percent solids by weight to 25 to 30 percent solids by weight.

Total sludge generation for both hydroxide and sulfide systems will be somewhat higher than the rates shown in Figure 29. The additional solids are caused by the presence of lime solids, suspended solids in the wastewater feed, and insoluble byproducts resulting from neutralization. For treating waste streams to remove heavy metals, the additional solids should be approximately the same for

Figure 29.

Sludge Generation Factors for: (a) Precipitation of Metals and (b) Hexavalent Chromium Reduction

insoluble sulfide and hydroxide systems. For chromium reduction, SO_2 reduction systems often require the wastewater to be acidified, and the quantity of alkali for subsequent neutralization is larger than that required with sulfide reduction. Consequently, the additional lime required for neutralization with SO_2 reduction will result in more lime solids in the sludge.

Licensing fees for the use of ISP to treat wastewater are charged annually and are determined by the flow rate of wastewater treated. This fee is small, however, compared with other costs typically associated with wastewater treatment.

Equipment Costs. The actual total installation costs for the three ISP treatment systems described earlier are presented in Table 10. All three systems were installed in plants that had no existing treatment systems. The systems in Plants A and B are similar to the one illustrated in Figure 13. The costs presented also include duplexing of many of the pumps and reagent storage tanks, a control panel, and additional instrumentation not shown on the flow diagram. Plant C is a sulfide polishing system similar to the one shown in Figure 17. The installed cost of this system includes the additional equipment required by a polishing system—a second clarifier (to separate the insoluble compounds resulting from hydroxide neutralization) and a second polyelectrolyte feed system.

Much of the equipment in an ISP system is common to hydroxide systems. Cost data on wastewater treatment equipment for the metal finishing industry are presented in the EPA report, *Economics of Wastewater Treatment Alternatives for the Electroplating Industry.* Converting a hydroxide system to use ISP in many cases will require only the installation of a mixer/clarifier downstream of the existing clarifier and a feed system to meter the FeS and polyelectrolyte into the wastewater.

Table 11 presents the cost (including installation and hardware) of installing the following ISP process

Table 10.

Installation Costs for Three Sulfex™ ISP Treatment Systems

Cost component	ISP system cost ($1,000)		
	Plant A	Plant B	Plant C
Installation costs:			
Process equipment	175	92	NA
Underground tanks	36	48	NA
Shipping and installation	29	22	NA

Figure 30.

Comparison of Chromium Reduction Treatment Sequences: (a) Chemical and (b) Insoluble Sulfide

equipment components in an existing treatment system:

- Mixer/clarifier
- FeS reagent preparation and feed system
- Polymer feed system
- Control loops
- Suspended solids polishing filters

The installed costs presented for a mixer/clarifier are for a preassembled, skid-mounted component requiring only piping and electrical connections for installation. The FeS reagent preparation and feed system includes two FeS feed tanks with low-level alarms, two reagent pumps, a mixing tank, and a transfer pump; the costs are for skid-mounted, preassembled units, constructed of carbon steel (see Figure 16).

The costs presented for the polymer feed system are based on a system with two plastic polymer feed tanks and two positive displacement pumps with adjustable stroke. The skid-mounted, preassembled components are equipped with a low-level alarm and dilution water-mixing apparatus. Costs are given for two control loops: a reagent addition control system with a magnetic flow meter and flow counter (to match the addition of FeS and polymer with wastewater volumetric throughput) and a low-pH feed interruption control. The costs for suspended solids polishing filters are for dual mixed-media filters, skid mounted and sized so that one filter can process the maximum flow during backwash. The filters are equipped with a blower for low pressure air scouring, a backwash storage tank, and a pump to bleed the wash back into the system.

Cost Comparison of Conventional Chemical Reduction and ISP Chromium Reduction. Replacing a conventional chromium reduction system with reduction by FeS can be advantageous. In some cases, an operating cost benefit will result. Another advantage of reducing chromium with FeS is that the hexavalent chromium wastewater does not need to be segregated for individual treatment; it can be treated in the common neutralization/precipitation treatment sequence. Figure 30 defines typical treatment sequences for reduction of chromium by chemical means and using FeS. The FeS treatment

process eliminates the need to lower and raise the pH of the wastewater and results in a significant saving in acid and alkali reagent. Table 12 presents treatment and sludge disposal costs for the two chromium reduction systems shown in Figure 30. The chemical consumption factors assume that lime consumption is twice the stoichiometric amount required to neutralize the wastewater and precipitate the dissolved metals. The excess lime is needed to overcome buffering normally encountered when neutralizing waste streams. It is further assumed that lime solids equal to 50 percent of the mass of lime used in neutralization are present in the sludge. These lime solids result from precipitation of insoluble byproducts in the neutralization reaction as well as from the tendency for some portion of the lime used not to dissolve and add to the sludge volume. Consequently, the lime required in the chemical reduction treatment sequence to raise the pH from 2 to 8 results in considerable sludge generation.

Figure 31 compares the cost of treatment chemicals and sludge disposal for the two chromium reduction systems shown in Figure 30 over a range of hexavalent chromium concentrations in the wastewater. A cost savings can be realized for FeS reduction compared with conventional chemical reduction. For wastewaters requiring twice the stoichiometric FeS dosage, a treatment cost advantage exists over treatment of wastewater containing less than 50 ppm Cr^{+6} by SO_2 reduction and that containing less than 100 ppm Cr^{+6} by $NaHSO_3$ reduction. For FeS reduction systems requiring twice the stoichiometric dosage rate, a savings in solid waste disposal costs also would be realized for treatment of wastewater containing less than 150 ppm Cr^{+6}. At higher FeS dosage requirements, such as 4 times the stoichiometric demand, chromium reduction using FeS is more economical for treatment of dilute chromium waste streams.

It is important to point out that the preceding comparisons are based on typical operating conditions and reagent costs; a comparative analysis for a specific plant should use actual operating data (e.g., reagent consumption and sludge generation).

Table 12.

Cost Basis for Comparison of Chemical and Insoluble Sulfide Chromium Reduction Treatment Systems Shown in Figure 30

Parameter	Cost[a]			
	Treatment[b]		Sludge disposal[c]	
	$/lb Cr^{+6}	$/1,000 gal wastewater	$/lb Cr^{+6}	$/1,000 gal wastewater
Chemical reduction:				
Sulfur dioxide	0.43	0.57	0.16	0.12
Sodium bisulfite	0.82	0.68	0.16	0.12
Insoluble sulfide reduction:				
Ferrous sulfide at dosage equal to 2 times stoichiometric requirement	1.58	0.03	0.21	0.01
Ferrous sulfide at dosage equal to 4 times stoichiometric requirement	3.12	0.03	0.33	0.01

[a]Total treatment cost is based on both mass of chromium reduced and volume of wastewater treated.

[b]Based on lime at $0.035/lb, sulfur dioxide at $0.15/lb, sodium bisulfite at $0.20/lb, sulfuric acid at $0.05/lb, and ferrous sulfide at $0.43/lb.

[c]Based on disposal at 25 percent solids by weight at a cost of $0.10/gal sludge.

Note.—1979 cost basis. Sulfur dioxide and sodium bisulfite consumption is equal to 2 times the stoichiometric requirement at a hexavalent chromium (Cr^{+6}) concentration of 50 ppm. Lime consumption is equal to 2 times the stoichiometric requirement for unbuffered waste streams. Lime solids are 50 percent of lime dosage and contribute to sludge volume.

Cost Comparison of ISP Polishing and Total Metal Treatment. Converting all metals in a waste stream to metal sulfides via sulfide precipitation uses considerable FeS and results in a large volume of waste solids. Separation of the precipitated metal hydroxides from the wastewater before polishing with sulfide precipitation can reduce both reagent consumption and solid waste generation. In a polishing application, the FeS reagent demand is a function of the dissolved metal concentration in the wastewater after hydroxide precipitation/clarification. Conversion of a sulfide precipitation system

Figure 31.

Costs of Treatment Chemicals and Sludge Disposal for Chemical and Insoluble Sulfide Chromium Reduction

to a polishing system requires installation of a second clarifier and polyelectrolyte feed system to separate the precipitated metal hydroxides from the neutralized wastewater before adding the sulfide reagent.

The reagent consumption and solid waste generation factors associated with treatment of the total metal load were presented in Figure 28. To estimate reagent requirements for a sulfide polishing system, it is necessary to determine the concentration of the metals in the wastewater after hydroxide neutralization/precipitation/clarification. Reagent consumption ranges between 1.5 and 4 times the stoichiometric demand for polishing systems. Compared with the reagent consumption factors presented in Figure 28, the sulfide precipitation polishing system at Plant C required an FeS dosage rate of 40 ppm in the wastewater. Note, however, that this system did not have a significant level

of hexavalent chromium in the wastewater; hexavalent chromium is not removed by hydroxide precipitation, and reagent demand for chromium reduction will be the same for sulfide polishing or sulfide precipitation systems.

Plant A uses ISP for total treatment of the metals in the wastewater. Table 13 presents the costs of wastewater treatment using ISP as a polishing step compared with its use to precipitate the total metal load at Plant A. The major cost saving results from reduced FeS consumption; the required FeS dosage is reduced by separation of precipitated metal hydroxides before the addition of the sulfide reagent.

Based on the savings indicated in Table 13, a profitability analysis of the investment required to convert to a polishing system is presented in Table 14. The $26,000 investment required for the conversion would have an average

Note.—1979 cost basis.

after-tax return on investment of 13 percent.

The costs of FeS reagent and solid waste disposal for ISP systems and sulfide polishing systems are compared further in Figure 32 for each 1,000 gal (3,785 l) of wastewater treated at various metal concentrations. The solid waste disposal cost estimate assumed disposal of the sludge at 25 percent solids by weight at a cost of $0.10/gal of waste and that both sludges would dewater to the same level. The FeS reagent cost for the polishing system was derived from a required FeS dosage rate of 40 mg/l of wastewater. Figure 32 presents the difference in cost, rather than total treatment costs, of sulfide reagent and solid waste disposal for sulfide precipitation and sulfide polishing systems. Other costs associated with treatment should be similar for both systems.

Figure 32.

Treatment Cost of ISP vs. Insoluble Sulfide Polishing

A polishing system can achieve significant savings at higher wastewater metal concentrations. As an example, Figure 32 reveals that a system treating 3,000 gal/h (11,340 l/h) with a metal concentration of 100 ppm and requiring twice the stoichiometric amount of FeS would save $2.80/h—(B minus A) × 3,000 gal/h. At the same flow rate and metal concentration, the savings would be $5.70/h if the wastewater required 4 times the stoichiometric amount of FeS.

Using the savings shown in Figure 32, Figure 33 presents the return on investment for installing the additional treatment hardware needed for a polishing system over a range of metal concentrations and wastewater flow rates.

Figure 33.

Return on Investment of Additional Capital Required for Insoluble Sulfide Polishing System: (a) Treatment Requiring Two Times the Stoichiometric FeS Requirement and (b) Treatment Requiring Four Times the Stoichiometric FeS Requirement

Reprinted from ENVIRONMENTAL PROGRESS, November 1983

Dissolved Heavy-Metal Removal by Insoluble Starch Xanthate (ISX)

Case-history studies demonstrate that very low residual-metal concentrations can be achieved in the treated effluents.

R. E. Wing, U.S. Department of Agriculture, Peoria, Ill. 61604

ISX (insoluble starch xanthate), one of the simplest, most effective ways to reduce heavy metals in industrial wastewater, was originally developed at the U.S. Department of Agriculture, Northern Regional Research Center, Peoria, Illinois [1-7], under a grant from the Environmental Protection Agency. After internal ISX product research and development, Pollution Technology Systems of Garland, Texas announced formula changes that allow for mass-production capabilities, optimum heavy-metal uptake capacity, and the solution to shelf-life stability problems.

In January of 1980, ISX was introduced by Pollution Technology Systems as a commercially available product. ISX is allowing several industrial users to meet their present and future Public Owned Treatment Works (POTW), or Direct Discharge Statutory Water Quality Heavy Metal Limitations.

ISX offers industry a low-cost product requiring minimal capital investment for application of the treatment of industrial process and wastewater effluents. It is a highly cost-competitive product when compared to other known methods for final polish of process or effluent discharge water containing less than 10 mg/liter of heavy-metal ion contaminants in singular or complexed form.

ISX is a cereal grain-based product that is chemically cross-linked to make it insoluble in water and then xanthated to form an anionic polymer. When added to spent industrial process water containing dissolved heavy-metal cations, ISX exchanges sodium and magnesium ions upon contact for the heavy-metal cations.

Several case-history reports will follow, to show some of the ways ISX is being used to successfully remove toxic heavy metals from industrial process waters, thus allowing these industries to achieve the proposed Best Available Technology (BAT) and Best Practical Technology (BPT) discharge limits [8-9].

CASE HISTORY I

In 1980-1981, a large southeastern Company found it necessary to upgrade their waste-treatment plant in order to maintain compliance with their water quality-based direct discharge permit for heavy metals. (Table 1 defines the Company's operations.)

All process wastewaters are segregated in the manufacturing facility, then flow 400 meters to the segregated holding basins at the waste-treatment facility (Figure 1). Cyanide destruction occurs at pH = 10.5 with chlorine. After an approximate 90-minute contact time, the pH is lowered to 9.0 with additional chlorine to complete the destruction of cyanate to carbon dioxide and nitrogen.

Chromium (VI) is reduced to chromium (III) by the addition of sulfuric acid and SO_2. The reduction takes place at

TABLE 1. MANUFACTURING OPERATIONS

Figure 1. Waste-treatment facility.

pH 2.5 with a contact time of approximately 90 minutes. The alkaline/acid/oil waste stream is initially treated with alum to remove emulsified oil in a dissolved-air flotation (DAF) unit. All wastewaters from the three holding basins flow to the mix tank after initial treatment. The average initial copper concentration is 30-40 mg/liter unless plating-tank dumps are made, which will increase the copper and other metal concentrations from 100 mg/liter to as high as 1,000 mg/liter. The initial pH of around 6.0 is adjusted to 9.5-10 with caustic (25%) in the mix tank (40,000 liter). The wastewater then flows to the solids contact unit (300,000 liter lamella clarifier). Before the waste-treatment plant was upgraded in 1981, lime (227 kg/day) and an anionic polymer (3.6 kg/day) were metered into the contact unit to increase the pH and aid in solids formation settling. Now only 45 kg lime is required (pH = 10.5).

As the wastewater (1325 liter/min) leaves the clarifier the pH is adjusted to 7.0-8.0 with sulfuric acid (94%) and the copper concentration ranges from 0.5-5 mg/liter. Before 1981, the wastewater went to a holding pond before discharge to a tertiary pond, then on to a creek. Now, the water flows to the ISX contact tank prior to four continuously backwash sand filters.

ISX (23 kg) is premixed with water (1438 liter) in a 1500 liter tank. ISX (15.8 g/per min or 3 liter/min) is metered into the ISX contact tank. The ISX treated water gravity flows to the alum tank. Initial lab studies showed that alum was needed for better floc formation. However, under actual conditions, the alum addition is not necessary. Therefore, considerably less sludge is generated.

As the wastewater gravity flows to the polymer tank, cationic polymer (1 mg/liter) is added from the polymer premix tank (1.9 kg/1900 liter). The wastewater is pumped to a flocculator tank for conditioning before it flows through the four parallel sand filters.

The wastewater is analyzed every two hours for copper and other metal contact, usually (0.3 mg/liter), as it flows to the holding pond (Figure 2). The backwash from the sand filters is continuously returned to the mix tank and/or the clarifier.

The State discharge limit to the creek is 136 g (average) of any metal per day with a daily maximum of 272 g/day.

PLOT PLAN

Figure 2. Plot plan.

Daily flows of 1.5 million liter/day with metal concentrations of approximately 0.08 mg/liter allow the company to meet its applicable discharge limits.

The sludge from the clarifier goes to one of two sludge lagoons. Periodically, it is pumped to the centrifuge following treatment with cationic and anionic polymer, and dewatered to 15% solids. The sludge is firm to the touch and is hauled to a Class 1 landfill. Company investigations are presently underway to delist the sludge.

Table 2 shows capital-cost information.

CASE HISTORY II

A Connecticut electroplating company, doing copper, chrome, and nickel plating, uses ISX on a precoated filter for a final polish. All plating processes have individual dead rinses, followed by two counter-flow rinses (Figure 3). Wastewaters are segregated for cyanide destruct with hypochlorite and chrome reduction with metabisulfite. All rinses, 410 liter/min, flow to a common sump for pH neutralization to 9.0 with caustic. The neutralized rinse water is transferred to combined holding and surge tanks (45,000 liter each), where it is continuously fed through two ISX (34 kg each) precoated filters for removal of metal hydroxides and heavy-metal cations. ISX treated water is returned to holding tanks for 90 percent rinse water recycle (Table 3).

The ISX precoat is changed weekly. The sludge is hauled to a Class 1 landfill. All dead rinses are treated within the system on a weekly schedule. Recycling water has dramatically reduced water and sewage surcharge costs (90 percent). End-product quality control has been improved by the use of more stable rinse-water temperatures and known conditions, independent of climatic and source-water variations.

Ni^{+2}	2.5	0.10

* Prior to ISX treatment

CASE HISTORY III

A Texas company uses ISX to remove residual cadmium before wastewater discharge. The rinse water (20 liter/min) is neutralized to pH 9 with caustic. The wastewater is then processed through a clarifier with upflow through an ISX sludge blanket. The treated effluent (Table 4) is discharged to a POTW after suspended solids removal with bag filters. The ISX usage is 6 kg every two weeks.

CASE HISTORY IV

A large Illinois communications equipment manufacturer recently upgraded its waste-treatment facility by installing an ISX metering system (capital cost = $2,000). All

* Prior to ISX treatment

process waters (950 liter/min) are not segregated in the manufacturing plant, so the presence of complexing and chelating agents did prevent heavy-metal discharge limits from being achieved.

Process waters are neutralized to pH 9.5 with caustic, and ISX (154 mg/liter) in a water slurry is metered into the treatment system. A 45-minute contact occurs before solids removal on diatomaceous-earth precoated filters. The treated effluent (Table 5) is discharged to a POTW. Fluoride removal is an added benefit using ISX.

CONCLUSIONS

The cited examples show that ISX can be used in several different ways to achieve very low residual metal concentrations in treated effluent for discharge or reuse. Table 6 shows additional ISX treatment results that are being achieved by a cross-section of industrial categories. In addition to application in metal-finishing wastewaters, ISX is presently being evaluated for vanadium removal in boiler wastewaters from public utilities and as a selective flocculant in the recovery of sulfide-bearing ores.

Robert E. Wing obtained his B.A. in chemistry from Millikin University and his Ph.D. in chemistry from Southern Illinois University-Carbondale. He joined the Northern Regional Research Center in 1968 as a research chemist and has been working on the development of starch-based products for industrial applications. During the last 10 years he has developed several starch-based products which have found use as heavy metal scavengers in water pollution control. He has also developed several treatment processes effective for heavy metal removal from printed circuit and plating on plastic rinse waters. He is a member of the American Electroplaters Society, American Chemical Society, and Sigma Xi and a part-time instructor at Bradley University. He has authored or coauthored 60 scientific papers and has 6 patents.

Insoluble Starch Xanthate(ISX) has been proven to be one of the simplest and most effective ways to reduce heavy metals in industrial wastewaters. The product was originally developed by the U.S. Department of Agriculture under a grant from the Environmental Protection Agency.

ISX is a cereal grain based product that is chemically cross-linked to make it insoluble in water and then xanthated to form an anionic polymer. When added to industrial process waters containing undesirable levels of dissolved heavy metal cations, ISX exchanges sodium and magnesium ions upon contact for the heavy metal cations. ISX containing the entrapped heavy metal cations is then removed from the treated process water by gravity precipitation or filtration.

The ion exchange efficiency of ISX and its capacity for heavy metal ion exchange is determined from the specific chemical composition of ISX and the related molecular weight and valence of a given heavy metal element or combination of elements. Table 1 identifies the documented heavy metal capacity of ISX under typical conditions.

TABLE 1

Zn^{+2}	Zinc	21.0 : 1

ISX is effective over a pH range of 3-11 with maximum effectiveness at approximately a pH of 9.

Copper complexes (EDTA and Quadrol as examples) are most effectively removed at a pH of 3. Hexavalent chromium (VI) removal occurs at a pH below 3 and subsequent neutralization to pH 8.

The treated water is clear and free of turbidity with improvements shown in both BOD and COD. With proper application ISX treated water can be recycled for added cost savings.

Results obtained from laboratory bench scale treatment of industrial process waters with ISX are shown in Tables 2 and 3.

TABLE 2
ISX REMOVAL OF INDIVIDUAL HEAVY METAL CATIONS FROM PROCESS WATERS

METAL	INITIAL CONC., mg/liter	ISX, g.	RESIDUAL CONC., mg/liter

Ni^{+2}	2.93	0.050
Pb^{+2}	10.36	0.031

A process wastewater solution (1,000 ml) containing the noted mixture of heavy metals was treated with 320 mg of ISX at an initial pH of 4.6. The solution was thoroughly mixed for positive contact and adjusted to a final pH of 8.9. Following filtration the remaining heavy metals in aqueous solution were determined by atomic absorption analysis.

Pollution Technology Systems ISX users (Table 4) represent industries selected from a general cross section of applications located throughout the United States. These industries range from Aerospace, Brass Works, Electronic, Printed Circuit Board, Oil Equipment to Electroplating. The companies all have varying degrees of Federal, State or local environmental effluent discharge requirements or internal objectives to meet. Case history in-process applications of ISX show heavy metal cation removal effectiveness approaching 99 percent. These users of ISX are able to economically meet or exceed the most stringent local, state or federal wastewater discharge permit requirements.

ISX is a highly versatile product requiring minimal, if any, capital investment for application. It can be used for batch treatment, slurried into a continuous flowing process stream or used as a filter precoat. It is especially effective when used as a final polish to remove 10 mg/liter or less of heavy metal cations from industrial process wastewaters for water recycle or effluent discharge. ISX is ideally suited in overcoming wastewater treatment conditions that result from the different solubility characteristics of metals as a function of pH or in the presence of metal complexing agents such as ammonia, EDTA, tartrate and Quadrol.

Removal of Heavy Metal Pollutants from Wastewater Streams

JOHN E. HANWAY, JR. and RICHARD G. MUMFORD
Beamer/Wilkinson & Associates, Oakland, California
and
DENNIS J. BARTH
General Motors Corporation, Warren, Michigan

Manufacturing operations of many industries, such as automotive, plating, printing, and metal-finishing, generate wastewater containing heavy metal components (chromium, nickel, zinc, copper, lead, etc.). These metals generally, if present in any appreciable amount, are toxic to aquatic life, exert a cumulative deleterious effect on receiving streams, lower or destroy the efficiency of biological waste treatment systems, and can, in many instances, represent a threat to human health. For these reasons, regulatory agencies have promulgated rather severe restrictions on the allowable heavy metals content of industrial waste outfalls. The trend is toward even more stringent limitations in the future; proposed guidelines contain requirements that approach the quality of potable water, with allowable contents of some heavy metals in the microgram range. If these guidelines become a reality (and, likely, they will), conventional methods now in use for the treatment of wastewaters containing heavy metals will become marginal for satisfying the low levels of contaminants allowed. This situation will require the development of more efficient and, undoubtedly, more sophisticated methods for heavy metal removal from wastewaters.

The anticipated need for improved heavy metal removal methods provided sufficient interest to undertake an evaluation and development program to identify those methods whose performance most likely would satisfy the projected wastewater quality criteria. In the course of this study, two methods, previously developed to some degree by others and potentially capable of meeting the future quality characteristics of heavy-metal wastewater treatment, were evaluated; additionally, a third method, based generally on one of the two methods initially studied, was conceived and subjected to preliminary evaluation study. This latter method for the removal of heavy metals from wastewater streams appears to have considerable promise in meeting quality requirements and for commercial application in alleviating the pollutional problems associated with heavy metals.

REMOVAL OF HEAVY METALS

Interest in treatment of heavy-metal wastewaters has been evidenced in recent technical literature. Several excellent reviews have been published, as well as many descriptions of specific problems associated with heavy metals treatment. The recent concern and interest in mercury removal has perhaps accelerated the investigative work in this field, and, with the prospect of more restrictive control of the entire heavy metals spectrum, more comprehensive consideration is being given to the entire family of heavy metal components.

For example, Cadman and Dellinger[1] review a total of 26 different methods that, technically at least, are applicable to the removal of heavy metals from wastewaters. They cover the more common methods, such as precipitation as hydroxides and sulfides, ion exchange, and extraction, as well as some of the more unusual and specialized treatments, among which are ion removal by a rotating electrode, paper chromatographic separation, radiation and magnetic field treatment, and biological ion removal. The results cited by Cadman and Dellinger apparently, for the most part, are from carefully-controlled laboratory tests or from very specialized mini-scale applications. They provide no evaluation of the performance that might be expected of these methods in commercial practice.

Argo and Culp[2] reviewed in detail the more common methods of heavy metal removal that could logically be applied to sanitary wastewater reclamation so that the treated wastewater could be utilized as an injection barrier for the prevention of sea water intrusion in the southern California area. These included chemical treatment, mixed-media filtration, and carbon adsorption. In part 2 of their paper, Argo and Culp reported the results of a pilot-plant investi-

gation of these methods for removal of heavy metals from a trickling filter effluent. It was found that the combined treatment of lime coagulation and settling, mixed-media filtration, and activated carbon adsorption was especially effective in reducing the concentrations of cadmium, hexavalent chromium, zinc, and copper in the biologically-treated influent. Other heavy metal components were removed to a lesser degree or were present in the influent in such low concentrations that a reliable evaluation could not be made. It was observed, as might be expected, that the removal efficiency was dependent on the concentration of heavy metals in the influent. The problems that increased metal content of the treatment sludges might cause was not discussed.

Cheremisinoff and Habib[3] in a two-part plenary account on heavy metal removal from wastewater covered: 1) nature, sources, and uses) 2) toxicity and toxic effects; 3) analytical methods for detection; and 4) removal techniques. The reports concentrate on cadmium, chromium, lead, and mercury because of their widespread industrial use, their toxicity, and their possible frequent occurrence in wastewater effluents. Ion exchange and hydroxide precipitation were the major routes suggested as appropriate for the removal of these metals; however, little quantitative data is presented as to the performance of these various methods.

Dean et al.[4] described the use of chemical precipitation methods, electrodeposition, cementation, solvent extraction, reverse osmosis, ion exchange, and activated carbon adsorption for heavy metal removal. While they mention application to many of the heavy metals, the review is particularly directed to the recovery of copper from waste effluents.

Esmond and Petrasek[5] have reported the fate of various metals in a municipal activated sludge pilot plant study involving biological/physical and biological/chemical/physical (AWT) sequences. The results indicated that substantial amounts of metallic constituents were removed by either method of treatment; influent concentrations were quite low and variable, however, and poor removal efficiencies were evident for such metals as lead, nickel, copper, cadmium, barium, and arsenic. The results would seem to discourage the use of waste pickle liquor as a source of iron salts in municipal waste treatment, notably in those applications where a high quality effluent is required.

Pugsley et al.[6] have described the removal of heavy metals from mine drainage waters by sulfide precipitation methods employing *p*H adjustment and either sulfide-containing reagents or a sulfate-reducing bacteria, *Desulfovibrio desulfuricans*. While further work was indicated, sulfide precipitation afforded low residual metal values and appeared to be a viable method of treating these discharges.

Fig. 1. Removal of Lead by Precipitation as a Function of Observed *p*H (Rohrer[7]).

More recently, Rohrer[7] investigated a number of chemical precipitants for removal of lead from wastewaters. The precipitants included lime, caustic soda, soda ash, trisodium phosphate, and combinations of these compounds. The results of his work are indicated generally in Fig. 1. With the exception of trisodium phosphate, residual lead levels with the individual reagents were in excess of 0.2 mg/liter; trisodium phosphate was effective to a residual level of 0.1 mg/liter. Based on typical regulatory agency requirements of residual lead contents of 0.05 to 0.1 mg/liter in industrial waste effluents, none of the individual precipitants seemed capable of consistently satisfying the limitations. Rohrer found that the most effective and economic combination was a trisodium phosphate-caustic soda mixture that was capable of reducing lead values to about 0.02 mg/liter. Figure 1 illustrates the rather narrow *p*H range where precipitate solubilities remain at a minimum when using mixtures of caustic soda-soda ash, lime, and soda ash as precipitants. These narrow ranges of operative *p*H require close maintenance of *p*H control points to provide consistent low level values of lead content.

With caustic soda, residual lead concentrations are minimal over a wider *pH* range.

Anderson and Weiss[5] patented a sulfide precipitation process that claims to avoid the generation of hydrogen sulfide and, through a coprecipitation mechanism with an additive compound, results in more complete removal of the pollutant ion than can be achieved by sulfide precipitation of the pollutant alone. In the process, a sulfide ion and a heavy metal ion that forms a sulfide having a higher equilibrium sulfide ion concentration than the sulfide of the heavy metal pollutant to be removed are added to the aqueous solution to be treated. As the sulfide of the added heavy metal is more soluble than the sulfide of the pollutant, the heavy metal pollutant ions are precipitated in preference to the added heavy metal ions. The added heavy metal ions also act as a scavenger for excess sulfide ions, thus preventing the formation of hydrogen sulfide and complex sulfide ions. In addition, the added heavy metal promotes coprecipitation of insoluble mixed metal sulfide compounds that leads to lower pollutant concentration in the effluent. A typical reagent pair suggested was sodium hydrosulfide (NaHS) and ferrous sulfate ($FeSO_4$). Using this procedure, residual concentrations of zinc, nickel, chromium, cadmium, copper, and iron of 0.05 mg/liter or less were claimed with simulated waste solutions.

Wing[6] described a novel method for removing heavy metals from wastewater employing starch xanthate produced from a highly cross-linked insoluble starch. This method was claimed to be highly effective in reducing heavy metal contents to the microgram level by forming an insoluble xanthate complex with the heavy metals present, thus permitting separation from the aqueous phase. It was suggested that a cyclic process could be used, including regeneration and reuse of the starch substrate and recovery of the removed metals. Wing's data were mainly collected during the treatment of relatively small volumes (50 mliter) of simulated wastewater solutions; copper, cadmium, chromium, mercury, and iron contents were reduced to below 0.01 mg/liter and nickel, lead, and zinc to below 0.05 mg/liter. Residual silver and manganese levels in the treated wastewater were somewhat higher than the levels attained with the other metals.

BACKGROUND OF THE PRESENT STUDY

The present experimental study was undertaken to evaluate available heavy metal removal methods that had 1) the potential for removal of heavy metals, particularly lead, to low residual levels (i.e., less than 0.050 mg/liter) and 2) the potential to be practically incorporated into high-volume industrial wastewater treatment applications. The study of the available literature had generally indicated that hydroxide precipitation methods would not be suitable because of their inability to satisfy the low levels of residual metal contents desired. In addition, the results of such processing were generally available. Sulfide precipitation methods seemed capable of perhaps satisfying quality criteria for the treated wastewater, but, historically, these methods have been plagued by operational problems, such as hydrogen sulfide evolution, that have limited their commercial application. If some of these operational problems could be eliminated, then perhaps a better climate for industrial application would result. The starch xanthate process was of interest because of its apparent ability to produce residual concentrations of heavy metals within the range of interest in the present work. Two general approaches, thus, sulfide precipitation and starch xanthate treatment, as exemplified by Anderson and Weiss and by Wing, respectively, seemed to fit the requirements of the evaluation program. These two approaches had been the subject of some experimental study by others, and the results appeared promising for industrial use. The exploratory experimental program thus was directed initially to the evaluation and applicability of the sulfide precipitation and the starch xanthate methods of heavy metal removal.

Bench-scale experimental work was undertaken with single-component (lead-bearing) simulated wastewater solutions and with multi-component simulated and actual wastewater solutions. Simulated wastewater solutions were employed to determine the general effect of pertinent parameters and to establish a nominal range of optimum performance. The results then were confirmed and expanded with actual multi-component wastewater samples. Laboratory glassware was used as reaction and sedimentation vessels throughout the studies, and sample volumes used throughout the program ranged from 0.5 to 20 liters. In general, standardized jar-treatment procedures were used throughout the work, with reaction contact being made under gently agitated conditions. The major variables studied were reaction time, temperature, amount of reagent, and, in some cases, sequence of reagent addition.

The experimental tests were evaluated by the level of residual metals in the treated solution. Analysis of the solutions for metal content was accomplished by atomic absorption spectrometry using a carbon arc vaporization chamber.

SULFIDE PRECIPITATION TESTS

The sulfide precipitation process proposed by Anderson and Weiss provided excellent technical per-

formance with both simulated and actual wastewater samples with respect to the residual heavy metal levels in the treated wastewater. Lead, zinc, copper, chromium, and iron contents all were reduced to below 0.05 mg/liter, employing two to three times the stiochiometric amount of sulfide precipitant (NaHS and $FeSO_4$). In some instances, lead and copper levels were less than 0.01 mg/liter. While some evolution of hydrogen sulfide was noted during the various tests, it was effectively eliminated by minor modifications in the manner in which the reagents were added to the reaction vessel.

As is common with many precipitation processes, sulfide precipitation of heavy metals produces substantial quantities of residual sludge. In some respects, particularly with regard to subsequent oxidation, solubilization, and leaching of the contained metal values, the sulfide sludges are more difficult to dispose of than are hydroxide precipitates. Because of dilution with extraneous materials, such as lime, it is not normally practicable to consider recovery and reuse of the contained metal values.

Primarily because of the sludge production noted in the sulfide precipitation process, it was concluded that this method would not yield a permanent and positive solution to the removal of heavy metals from industrial wastewaters. While it was capable of producing effluent qualities that would satisfy projected limitations and could be used as a stop-gap measure if necessary, its long-term use would undoubtedly be characterized by problems in sludge disposal and the improbability of any ultimate metal recovery from the residual sludges. Its utility from a widespread industrial usage standpoint appears to be severely limited.

STARCH XANTHATE TESTS

Technical performance of the starch xanthate heavy metal removal method as described by Wing likewise was excellent insofar as the levels of residual metal contents were concerned. The use of starch xanthate that had been prepared in the laboratory from highly cross-linked starch and dried prior to contacting with simulated and actual wastewater samples produced residual lead contents well below 0.05 mg/liter (ranging down to about 0.01 mg/liter). Residual copper contents at the same conditions were about 0.06 mg/liter. The results of these tests indicated that the starch xanthate process was capable of attaining extremely low levels of lead and copper in the treated wastewater.

On the other hand, the characteristics of the precipitated starch xanthate residue, while quite small in amount as compared to the degree of sludge production in more conventional heavy metal removal processes, were not particularly favorable. Sedimentation of the suspended material was found to be slow, and often the supernatant liquid was turbid and cloudy. On filtration, the suspended material and residue formed a homogenous and cohesive mass on the filter that impeded the rate of filtration and could only be removed by scraping. The filter cake was sticky and gummy (vis-a-vis typical starch suspensoids) and had a moisture content of 60 to 80% water. Its properties would make it difficult to handle on a commercial scale. The required steps of removing the precipitated metal, re-xanthating the spent starch, drying the re-xanthated starch, and recycling to the process would present a number of formidable problems in an industrial application.

The starch xanthate process was claimed to have an inherent capability to increase the *p*H of the contacted wastewater. While the use of starch xanthate with the simulated wastewater solutions (*p*H 6.5 to 7) resulted in residual lead contents below 0.050 mg/liter, the *p*H of the solutions did not change appreciably. In further tests, adjustment of the *p*H to 8 with lime or caustic made for somewhat better and more consistent results.

DEVELOPMENT OF THE CELLULOSE XANTHATE PROCESS

Prior to and during the bench-scale study of the starch xanthate process, the usefulness of some of the characteristics of the xanthate approach were recognized. The capability of removing heavy metals to an extremely low level, sufficient to meet projected limitations with a high degree of reliability, was a primary asset. The problem of disposal of large amounts of residual sludge seemed to be amenable to solution because of the small amount expected to be produced and the opportunity to recover metal values and to recycle process reagents appeared promising. These characteristics would mitigate many of the objections so often advanced with respect to contemporary conventional metal-removal methods.

On the other hand, the evaluation program did show that the starch xanthate process possessed some disadvantages. The major deficiency was the nature of the starch xanthate-metal complex precipitate or residue formed following contact with the wastewater effluent, which would cause handling problems in commercial application. A somewhat less important, but nevertheless critical, factor was the lack of history of the commercial production of starch xanthate—considerable development and process complication would be necessary to ensure the availability of starch xanthate as a process reagent.

Consideration then was given to modification of

the xanthate approach in order to improve its utility for commercial application. It was theorized that if, in fact, the xanthate portion of the starch xanthate

Table I.

molecule represented the active site for metal immobilization, then any xanthate should be as equally effective for metal removal. The xanthates were reviewed to define those that might be more suitable than starch xanthate as far as materials handling and dewatering properties were concerned.

Cellulose xanthate, primarily because of its fibrous nature and secondarily because of its commercial production as an intermediate in viscose manufacture, appeared to possess the characteristics that would eliminate some of the difficulties encountered with the use of starch xanthate. In order to confirm its possible use, bench-scale evaluation of its performance was undertaken.

Jar tests were employed to study the parameters associated with the use of cellulose xanthate. The procedure involved contacting samples of simulated and actual wastewaters containing lead and other heavy metals with cellulose xanthate, either prepared in the laboratory or obtained commercially, under various conditions. Sample volumes of from 0.5 to 5 liters were used throughout the program, contacting was made under standardized conditions with gentle agitation, and solids separation was made by a combination of sedimentation and vacuum filtration.

Laboratory-prepared cellulose xanthate was made from cotton and paper towel stock by reacting the cellulose substrate with carbon disulfide and caustic soda. Metal removal in these first tests with laboratory-prepared cellulose xanthate were erratic, probably reflecting nonuniformity of xanthation of the laboratory-prepared material, as no investigation was made of optimum xanthation conditions. The results became more consistent after commercial xanthate was received and used in the evaluation program.

Table I shows the results of metal removal tests from samples of wastewater with the various forms of cellulose xanthate. The initial *p*H of the simulated wastewaters was about 6.9 and that of the industrial wastewater was about 3.5. The *p*H was adjusted in both cases to about 8 with lime slurry or with caustic prior to the contacting step. As can be seen, at a xanthate dosage of 90 ppm, residual values of lead and zinc in the industrial wastewater are quite low, 30 μg//liter or less. At the same xanthate dosage, copper and iron contents were acceptably low. Contact times of 30 min. were used in these tests; additional work indicated that this could be decreased to less than 15 min. with no significant decrease in metal removal. Temperature was found to have little effect, and the use of a coagulant polymer provided only a slight improvement in results.

With comparison to starch xanthate residues, the handling and dewatering of the cellulose xanthate-metal complex residue were significantly improved. The residue settled rapidly, leaving a clear supernatant, and the fibrous nature of the residue enhanced fast and efficient filtration. No data were generated during the evaluation study as to the actual difference in filtration rates between the starch and cellulose xanthate residues; visual observation, however, would indicate improvement of an order-of-magnitude scale.

Detailed capacity or loading studies were not undertaken. The adsorptive capacity of the cellulose

Fig. 2. Flowsheet of Cellulose Xanthate Process for Heavy Metal Removal.

xanthate would be expected to be a function of the degree of xanthation as indicated for the starch xanthate process. With the commercial cellulose used in this study (whose degree of sulfur substitution was not determined), it appears that a loading similar to that provided by starch xanthate should be possible before any significant deterioration of performance is encountered. This factor will require further study and development.

Data on the starch xanthate process indicate an inherent ability of the starch xanthate to adjust the *p*H of the wastewater to a value consistent with acceptable discharge criteria. This is ascribed to the presence of bound alkali in the xanthate product, which can be decreased by excessive washing of the material. In any case, this self-adjustment of the *p*H was not noted in the present study with cellulose xanthate. Many of the cellulose xanthate samples were washed thoroughly before use. It was necessary, therefore, to use external *p*H adjustment with lime slurry or with caustic to a final *p*H above neutral (*p*H 8) to insure consistent results. With the simulated wastewaters, whose initial *p*H was relatively high (6.5 to 7), the amount of lime or caustic required was negligible and did not contribute to sludge formation. With actual wastewater samples, the initial *p*H was much lower (3.5), and correspondingly more lime or caustic was required for *p*H adjustment. In the case of *p*H adjustment with lime, sludge formation was significant in such cases and complicated recovery of the spent xanthate. In most cases with the actual wastewater samples, *p*H adjustment was made with caustic so that sludge formation could be avoided.

Further work is needed to define more clearly the *p*H adjustment aspects of cellulose xanthate treatment so that external adjustment might be eliminated. It is apparent, however, that if external *p*H adjustment of low-*p*H wastewaters does prove necessary, the use of an insoluble base (lime) for such adjustment is undesirable because of sludge formation and the attendant complications involved with the recycling of the cellulose xanthate substrate.

COMMERCIAL APPLICATION OF THE CELLULOSE XANTHATE PROCESS

Figure 2 shows a simplified version of the commercial application of the cellulose xanthate process for heavy metal removal. The major steps indicated are wastewater contacting with the cellulose xanthate and removal of the heavy metals content, stripping of the metals from the cellulose by acid extraction, and re-xanthation of the cellulose substrate. There are several ways that these steps can be carried out. Batchwise operation, in which a quantity of cellulose xanthate is pulped with the wastewater stream, can

Fig. 3. Conceptual Commercial Application of the Cellulose Xanthate Process for the Removal of Heavy Metals from Wastewater.

be used, and after sufficient contact the residue can be separated by sedimentation or filtration, stripped of its metal content, re-xanthated, and returned to the process for additional treatment of wastewater. However, the physical characteristics of cellulose xanthate, particularly its fibrous nature, offer opportunities for potentially more desirable methods of operation. The fibrous nature of cellulose xanthate should allow the fabrication of porous mattes or elements having sufficient structural strength and stability to permit use in a flow-through reaction vessel that would allow application without the necessity for physical handling of the cellulose xanthate or substrate. This would permit the successive operations of wastewater contacting, metal stripping, and re-xanthation to be accomplished in place within the reaction vessel without the necessity of removing the cellulose xanthate or cellulose substrate after stripping from the reaction vessel. This concept is shown in Fig. 3.

In this instance, a porous cellulose substrate is contained in each of the three parallel reaction vessels where the steps of wastewater contacting, metal stripping, and cellulose re-xanthation are accomplished concurrently. By suitable arrangement of piping and control valves, the operation can be made continuous; automation can be provided so that unattended operation is possible.

No work has been undertaken on the extraction of metal values from the spent xanthate, recycle of the re-xanthated cellulose, or recovery of the metal from the stripping solution. Such effort will need to be made prior to full realization of the potential of the process. Analogous with the starch xanthate process, however, the metals could be removed by acid-stripping of the spent xanthate and would be available in a relatively concentrated solution for subsequent metal recovery. Possible routes to metal recovery include such conventional methods as electrolysis, cementation, or precipitation. Alternatively, if metal recovery is not to be accomplished, precipitation could be employed to immobilize the metals; this could probably be accomplished easier with the concentrated solution than with the entire wastewater flow. Obviously, metal recovery would seem the most desirable from an ultimate disposal standpoint even though, in most cases, the economic value of the recovered metals might not be a significant factor.

Consideration could also be given to the use of the cellulose xanthate process as a "polishing" operation subsequent to other methods of metal removal, where these methods are not capable of attaining the required low levels of contaminants in the effluent wastewater. As a matter of fact, it might be advantageous to combine a less efficient pretreatment method but one that facilitates metal recovery or minimizes sludge production with the cellulose xanthate treatment and to depend on the latter to reduce

the residual metal content to acceptable levels. There exist many possible combinations of this sort that would be possible, depending to a large extent on the specific characteristics of the wastewater and the environment in which it is generated.

CONCLUSIONS

While additional development work is required to refine many areas of the cellulose xanthate process for heavy metal removal, this preliminary evaluation has indicated that it does have the potential for effective treatment of industrial wastewaters. It has the most important capability of achieving low levels of residual metal content in the treated effluent, and specifically, lead, that will satisfy projected water quality criteria. For this purpose, it can be considered either as a replacement for or a supplement to the more conventional methods of heavy metal removal that may be marginal in providing the low levels of residual metals necessary. It offers this and also the potential of minimizing the excessive production of hard-to-handle residual sludges.

The cellulose xanthate process should be readily adaptable to a closed-cycle concept where recycle, recovery, and reuse of both reagents and products can be accomplished. Its operation would appear to be both simple and reliable and consistent with a high degree of automation, thus affording a less labor-intensive system than conventional methods of metal removal.

Indications are that insoluble starch xanthate can reduce cadmium from around 1 ppm to less than 0.2 ppb in minewater-type effluents.

CHELATION FOR METAL REMOVAL

Although no information on how the process works has been made available and no cost data has been released, the results described by HOLBEIN, et al. (1984) inserted below indicate a process which is capable of removing metals to a very low level on the one hand (e.g., chromium VI) or being very specific in its removal of one metal (e.g., Hg) in the presence of other metals.

ABSTRACT

Increased volumes and varieties of toxic heavy metal wastes from a number of industries, coupled with higher emission standards and dwindling waste repositories, have necessitated the introduction of greatly improved technology for the safe and effective handling of heavy metal laden wastes. Present and future requirements of toxic metal source reduction technology are best summarized by the terms "Concentrate and Contain"; concentrate, meaning improved efficiency of metal recovery and contain, meaning production of a metal waste form which can either be recovered and reused or transformed to a stable state where toxic metals remain imobile. This paper describes new technologies, the DeVoe-Holbein Technology, which provides highly efficient and effective means of waste metal closed-loop source reduction of aqueous heavy metal wastes from both nuclear and non-nuclear industries.

The DeVoe-Holbein technology consists of a novel series of synthetic compositions and various processes for their use. The compositions are highly efficient at metal recovery (typically achieving 99.99% source reduction) are selective for individual or groups of metals, allow high flow throughputs, are mechanically and chemically robust and stable and are completely regenerable with small volumes of regenerant.

Case studies are presented to illustrate how this new technology can be applied to the closed-loop recovery of mercury, chromium and radioactive fission products such as cesium and strontium. In addition, examples are shown to illustrate the effective recovery of metal finishing wastes such as cadmium, zinc, copper, cobalt, nickel and lead.

INTRODUCTION

Aqueous wastes laden with toxic heavy metals are generated by a large number of industries ranging from metal finishing operations to the nuclear industry. Such wastes pose an ever increasing threat to the environment. While the nuclear industry has handled waste problems by preventing the release of radioactive metallic wastes to the environment, the increasing volumes of such wastes together with the very long term time requirements for containment have necessitated improved methods for waste volume reduction and more stable storage forms for long-lived radioactive wastes.

Traditional methods of dilution and discharge of heavy metal wastes from metal finishing are now regarded as unacceptable. A number of technologies for the extraction of heavy metals from metal finishing wastes have been employed (1) Thus, hydroxide lime or sulphide precipitations of heavy metals have seen wide useage. However, these technologies generate large volumes of concentrated wastes which must be disposed of, in for e.g. landfill sites. Restrictions are now occurring in some locations as to the amounts of such relatively mobile and toxic waste which can be placed in landfills. In addition, precipitation methods often do not bring effluent residual metal concentrations to levels low enough to meet the emission standards. Other more efficient extraction technologies for plating wastes include ion exchange technology. However, regeneration of ion exchange materials can generate fairly large volumes of metal-laden waste which is mobile and therefore requires further treatment.

Surprising similarities can therefore be observed in the present and future requirements of new technologies for the treatment of aqueous wastes containing toxic metals in both the non nuclear and nuclear industries. These requirements are embraced by the terms concentrate and contain; concentrate, meaning improved efficiency of metal extraction and contain, meaning producing a waste form which can be recovered and re-used or transformed to a stable state where the toxic metal remains imobile. This paper describes recently developed technologies which meet these requirements.

NATURE AND DEVELOPMENT OF DEVOE-HOLBEIN TECHNOLOGY

DeVoe-Holbein technology consists of a family of new synthetic compositions and the processes and technology related to their use. The origins of this technology stem from the basic research of Drs. DeVoe and Holbein, both biochemists who specialized in metal metabolism in biological systems.

All living cells have requirements for a number of metals

in their nutrition such as Fe, Ni, Co, Cu, Zn, Mn, Mg, Na and K. Throughout evolution, living cells have developed specialized chemical mechanisms to ensure that they successfully obtain their required metals but at the same time do not allow toxic levels of these metals to accumulate inside the cells. Similar mechanisms are used to sequester various non essential but highly toxic metals such as Cd, Hg, and Pb, which can often appear in a cell's environment. DeVoe and Holbein used the biological metal extraction and recovery mechanisms as model systems to create synthetic mechanisms which would accomplish similar high efficiency metal extraction and recovery but without employing living cells. This work was initiated in 1980 and has progressed rapidly and continuously. As a result of this entirely new approach, a series of novel compositions has been developed.

Each composition was designed to achieve the necessary selectivity while in the presence of other competing ions. All the compositions share the general features of high extraction efficiency (typically 99.99% efficient), complete regenerability with small volumes of regenerant (typically 0.5 to 2 bed volumes of regenerant), high mechanical and chemical stabilities (no swelling or compaction even at high flow rates of 50 bed volumes per hour or abrupt changes in pH), and freedom of release of toxic components. The DeVoe-Holbein technology has been successfully applied to a number of challenging problems from the nuclear and non nuclear industries both in the laboratory and in the field (see below). Application of this technology has emphasized the achievement of closed-loop recovery of waste metals. In addition, the compositions themselves, after their useful lifetime of numerous loadings and regenerations, can be economically utilized as raw materials in the manufacture of other products of existing commercial value.

PERFORMANCE CHARACTERISITICS OF DEVOE-HOLBEIN COMPOSITIONS

DeVoe-Holbein compositions are particulate chemical compounds made to a number of particle size specifications. Most studies with the compositions have employed fixed bed columns of various sizes and diameters. Thus, small scale laboratory testing has employed small glass cylindrical columns with bed volumes ranging from 3 ml to 7 L, whereas, a two column prototype water treatment plant built in Holland to test flows up to 4,000 L per hour incorporated 140 L fixed beds. Figure 1. illustrates the principle testing scheme common to the various testing scales.

Efficiency of Metal Capture

Efficiency of metal capture of any system will directly influence the level of residual metal in the treated effluent stream. DeVoe-Holbein compositions all display very high metal

TABLE 1

The Efficient Capture of Some Toxic Heavy Metals of Importance to the Hydrometallurgical and Metal Finishing Industries by DeVoe-Holbein Composition

Toxic Metals	DeVoe-Holbein Composition	Influent Concentration	Effluent Concentration [a]	Capture Efficiency % [b]
Cadmium	DH-516	674 ppm	< 1.0 ppb	≥99.99
Chromium	DH-524	694 ppm	< .01 ppm	≥99.99
Copper	DH-520	38 ppm	< 1.0 ppt	≥99.99
Lead	DH-501	42 ppm	<42. ppb	≥99.99
Mercury	DH-573	12 ppm	< 1.0 ppb	≥99.99
Nickel	DH-507	0.10 ppm	< 1.5 ppt	≥99.99
Zinc	DH-508	6.5 ppm	< 0.8 ppb	≥99.99

TABLE 2

The Efficient Capture of Some Metals of Importance to the Nuclear Industry by DeVoe-Holbein Compositions

Toxic Metal	DeVoe-Holbein Composition	Influent Concentration	Effluent Concentration [a]	Capture Efficiency % [b]
Cobalt	DH-502	1.2 ppm	< 20 ppt	≥99.99
Cesium	DH-566	7.8 ppm	< 2.0 ppt	≥99.99
Iron	DH-506	34 ppm	< 34 ppb	≥99.99
Strontium	DH-566	526 ppm	< 1.0 ppb	≥99.99
Thorium	DH-502	139 ppm	< 0.14 ppb	≥99.99
Uranium	DH-506	24 ppb	< 1.7 ppb	≥99.99

Notes: Table 1 and 2

[b] Capture efficiency determined as % reduction in influent concentration; values are greater or equal to those shown due to detection limits of effluent metal concentration

capture efficiencies both in the laboratory when tested with laboratory-formulated metal effluents and in the field when tested with actual metal-laden waste waters of variable make-up. Table 1 illustrates the high capture efficiencies obtainable in the laboratory with test metal solutions of importance to metal finishing and hydro-metallurgical operations. The very high efficiencies of capture of metal result in treated effluents with extremely low metal concentrations. This is highly desireable when recovering highly toxic metals such as Hg, Pb or Cr from waste waters and mandatory when treating radioactive metallic wastes with long-lived high energy radionuclides, such as Cs, Sr and Co. These high capture efficiencies have also been obtained in the treatment of actual waste waters containing variable amounts of target and competing metals (see Industrial Applications). Table 2 illustrates the similar high metal capture efficiencies obtained with metals of importance to the nuclear industry.

The DeVoe-Holbein compositions, in general, exhibit their high capture efficiencies up to the capacity of the particular compound, with a sharp breakthrough occurring after saturation of the composition. A typical breakthrough curve is shown in Figure 2 where the DeVoe-Holbein DH 520 has been used for Cu removal from a relatively concentrated metal solution. In addition, high efficiencies are obtained at low (1 bed volume per hour) and high (50 bed volumes per hour) flow rate. The capacity at saturation of a composition for a metal depends on the composition and the metal in question, with capacities generally falling in the range of 5 grams of metal to 30 grams of metal per kilogram of composition (per cycle of use). The number of regenerations obtained over the life of the composition is relatively high (see below) and, thus, substantial amounts of metal can be recovered (see industrial applications) with the DeVoe-Holbein compositions.

Selectivity of Metal Capture

Most of the DeVoe-Holbein compositions display high levels of selectivity for the metals or group of closely-related metals for which they were designed. Selectivity is assessed in the laboratory by using identical columns of a particular composition to treat solutions of different metals, all at the same concentration, temperature and flow rate. A series of breakthrough curves for the different metals is thus obtained and the volume passed before breakthrough of a given metal is directly related to the specificity of the test composition for the metal. Figures 3 and 4 display the slectivities of two different DeVoe-Holbein compositions for various metals. The selectivity of composition DH 506 for iron and its lack of specificity for Cd can be observed in Figure 3. Composition DH 501 on the other hand does not select Co, Fe or Cd but is highly selective for Cu (Figure 4). Similar results demonstrating individual or group selectivities have been obtained for other DeVoe-Holbein compositions. Selectivity and specificity of a particular

composition are somewhat functions of the pretreatments used with the particular composition and the conditions under which the metal solution or waste water are treated. Thus, in many instances selectivity and specificity can be altered (broadened or narrowed) to meet specific requirements of metal extraction.

Another test for specficity demands the capture of a test metal from a complex solution containing a number of other metals. Figure 5 demonstrates the ability of DeVoe-Holbein composition 506 to selectivity remove iron from artifical sea-water. Here, one can observe the radical differences observed between the highly selective DeVoe-Holbein composition and the currently used selective ion exchange resin and strong cationic exchange resin. The latter either quickly became saturated with competing cations from the solution or were highly interfered with by competing cations due to their lower selectivities.

Selectivity of DeVoe-Holbein compositions for metals can also be observed in many other cases (see for e.g. mercury removal from complex solutions in industrial applications, below).

FIGURE 2

FIGURE 3

FIGURE 4

FIGURE 5

Regenerability

Regenerability of a metal capturing resin or compostion is of great importance in almost all applications involving the recovery of toxic metals from waste waters in the non-nuclear industries. Regeneration of the ion exchange resins commonly employed for such applications can present problems, due to the large volumes or regenerant required to remove the bulk of the bound metal. This creates a secondary problem of treatment and disposal or recovery of relatively dilute metal from large volumes of relatively expensive regenerant.DeVoe-Holbein compositions are fully regenerable and, typically, small amounts of regenerant are required to displace the bulk of the bound metal. A comparison in regeneration ease between a strong cationic exchange resin and a DeVoe-Holbein composition is shown Figure 6. In this test, identical size beds of both materials were used, they were both used to capture similar amounts of cobalt (60 Co was used as a tracer to aid the quantitation in the regenerant effluent) and both were regenerated with 2N HCl. It should be noted that all the Co was removed from the DeVoe-Holbein composition in a single bed volume of regenerant but incomplete removal of cobalt was observed with the cation exchange resin even after many bed volumes of regenerant had been passed over the column.

FIGURE 6

Studies with a variety of DeVoe-Holbein compositions, at different scales and employing bed volumes between 3 ml and 140 L have demonstrated a general ease of regeneration of the compositions. Virtually 100% of the bound metal can be collected from the saturated compositions in volumes of regenerant between 0.5 and 2.0 bed volumes. In a full scale test using the pilot water treatment plant with one 140L composition column operating, influent cadmium at 2500 ppm in waste water was successfully extracted to produce a processed effluent with less than 0.01ppm Cd. Approximately 80% of the composition-bound Cd could be displaced in 15% of one bed volume of regenerant and virtually 100% was displaced with two bed volumes of regenerant. The ease of the regeneration of the DeVoe-Holbein compositions therefore affords some great advantages in the closed-loop recovery of metals. Small volumes of regenerant containing concentrated recovered metal are readily amenable to either primary metal re-use, waste immobilization or secondary metal re-use.

Other Characteristics

The DeVoe-Holbein compositions, because of the primary substrates employed in their manufacture, are resistant to relatively harsh treatments of acids and bases, abrupt changes in pH and flow rate and high dose exposure to radiation. Their mechanical stabilities allow high flow throughputs, with up to 50 bed volumes per hour, while still permitting high efficiency metal capture in a stable bed. The physical and chemical qualities of the DeVoe-Holbein compositions are of paramount importance in applications in the nuclear industry. Compositions, laden with highly radioactive metals, can either be regenerated to achieve high volume reduction factors or can be incorporated directly in the loaded form into waste transformation schemes, principally vitrification of the laden composition. This can be done using either existing vitrification technology or with a new vitrification process specifically designed for the DeVoe-Holbein compositions (see below).

INDUSTRIAL APPLICATIONS - CASE STUDIES

Mercury Recovery from Incinerator Scrub Water

Mercury remains one of the most toxic heavy metals to all life forms. This is due not only to its outright toxicity in low concentrations but also due to the ease with which it is transformed in the environment to more mobile and toxic forms. As a result, very high standards are in place throughout the world to ensure minimal release of mercury to the environment. However, mercury is still widely used in a number of industrial processes and appears in waste waters. Mercury containing batteries are widely used in a number of consumer electronic devices. As a result, there is a growing amount of municipal waste containing spent mercury-laden batteries. In Japan, municipal waste is often incinerated with flue gases being water scrubbed. This generates large volumes of waste water containing substantial (7 to 15 ppm) Hg. DeVoe-Holbein International N.V. has been working with a major Japanese water treatment company on this important problem .

The best available technology up until this study for this problem has involved conventional sulphide precipitation as the primary treatment method of the mercury waste water. The major disadvantages reported for this treatment are threefold. Sulphide precipitation is relatively difficult to control in attempts to maximize Hg precipitation. Even at best, sulphide precipitation does not produce treated effluents with low enough mercury concentrations. In addition, the large volumes of mercury-laden precipitate are relatively labile and mobile when disposed of in for e.g. landfill sites. The incomplete effectiveness of the sulphide

precipitation primary treatment dictates a secondary treatment scheme. This has been attempted with currently-available chelating resins. However, these have not been regenerable. Thus, the polishing resins are disposed of by incineration, i.e. the mercury is once again mobilized up the incinerator stack. Therefore, it can be seen that the conventional technology applied to this problem falls far short of providing a closed-loop source reduction of the mercury.

The DeVoe-Holbein composition DH-573 which had been developed for Hg capture and shown effective in the laboratory (Table 1) was examined for its utility for this problem. Samples of incinerator srub water without prior treatment and containing between 7 and 12 ppm Hg were brought to the laboratory for analysis and test work. Table 3 shows a partial analysis of this waste water before and after treatment with composition DH-573. Two important results can be appreciated from this data. First, the wastewater is relatively rich in a number of cations, including Hg, but composition DH 573 removed only Hg from this waste water. The second point is the complete removal of Hg from the waste water by a single passage through a column of DH-573. Figure 7 shows the ICP (Inductively coupled plasma emission spectrometry) spectra for the untreated and treated waste waters in the region for Hg detection (194.23 mm). More sensitive analysis, using atomic absorption spectrophotometry with cold vapour analysis for Hg, has shown that this waste water when treated with composition DH-573 contains Hg at residual concentrations below one ppb, the detection limits for the most sensitive available equipment. Studies, using the effluents from the currently employed sulphide precipitation which contain Hg at approximately 0.1 ppm, have shown a similar high efficiency and specific removal of Hg to below the limits of detection. The relatively large outputs of a typical incinerator scrubbing system (150,000 L)per day demand that any column treatment scheme be able to meet high throughputs, preferably using high flow rates. This is another limitation encountered with the currently employed polishing resin as relatively low rates (less than 10 bed volumes per hour) must be used for Hg polishing. The DeVoe-Holbein composition DH-573 effects equally high Hg removal efficiencies at flows between lo and 30 bed volumes per hour (the highest as yet tested) (Table 4.)

The DeVoe-Holbein composition DH-573 was also found to have a capacity of approximately 4.0 grams of Hg per kilogram of composition (approximately a 1 L bed of composition) and, most importantly, the composition was found to be completely regenerable (see Table 5). The full lifetime of this composition in this application is not yet known. However, the relatively corrosive primary incinerator scrub water did not at all affect the composition over five recyclings. Studies in the laboratory have shown DeVoe-Holbein compositions to be useful for at least 300 recyclings. DH-573 composition in preliminary tests was also found efficient at Hg removal at 80° C, the exit temperature of the waste water from the scrubbing system.

TABLE 3

SPECIFICITY OF DEVOE-HOLBEIN COMPOSITION 573 FOR MERCURY REMOVAL

Analysis of Incinerator Waste Water before and after Treatment

Element	Concentration ppm * Before Treatment	After Treatment
Mg	2.8	2.7

TABLE 4

Effect of Flow Rate on Hg Removal Efficiency with DH-573

Flow Rate Bed Volumes Per Hour	Influent Hg	Effluent Hg	Hg Removal Efficiency
10	11 ppm	≤1 ppb [a]	≈ 100%
20	8 ppm	≤1 ppb	≈99.99%
30	11 ppm	≤1 ppb	≈99.99%

[a] detection limits for Hg

TABLE 5

Regenerability of DH-573 for Hg Removal From Waste Water

Regeneration Number	Bed Volumes Passed to Breakthrough	Capacity Hg mg/kg Composition	Efficiency Of Regeneration	Bed Volumes of Regenerant Containing 100% Displaced Hg
1	≥230	≈4000	100%	≈2.0
2	≥230	≈4000	100%	≈2.0
5	≥230	≈4000	100%	≈2.0

The regenerant solution contains high concentrations of Hg. Studies have shown that this can be treated simply to generate reduced metallic Hg which can be collected readily Therefore all the Hg removed by this technology can be recovered in a form suitable to be returned to industry, thus closing the cycle for this toxic metal.

The DeVoe-Holbein technology, involving composition DH-573 for Hg removal, shows great promise for either primary treatment of Hg laden incinerator waste water or a greatly improved polishing treatment for sulphide precipitation effluents. Steps have now been taken to conduct full-scale field testing on site at a municipal incinerator facility in Japan.

Chromium (VI) Recovery from Plating and Boiler Wastes

Chromium is widely used in a number of metal finishing and plastic finishing operations. In addition, chromium is added to boiler systems for corrosion control. Therefore, chromium is commonly found in a number of industrial waste waters. Chromium VI is considered to be much more toxic in the environment than is chromium III and the emission standards reflect this fact. Chromium waste waters are usually handled by hyroxide precipitation with a prior reduction of Cr VI to Cr III in the case of chromate wastes. Two major problems attend this treatment scheme. The first is the large volume of Cr hydroxide wastes which must be disposed of as solid waste. This is a relatively labile waste form and the Cr can later be mobilized from the waste by natural processes and exihibit its toxicity. The second problem relates to the completeness to which Cr VI can be reduced and to which Cr III can be precipitated. Such treatments in practice often generate effluents with significant residual Cr VI or Cr III. Chromium can also be captured on conventional ion exchange resins but some resins are not regenerable and regeneration produces relatively large volumes of Cr laden waste in a mobile form.

Table 6 shows the make-up of three different chromium containing waste waters which have been analyzed and evaluated for treatment with DeVoe-Holbein technology. Example 2 is the effluent from conventional chromium reduction and precipitation of waste water from the aircraft industry. It should be noted that the residual 3,8 ppm Cr VI in this effluent is too high for normal discharge. The various effluents shown in Table 6 also contain a variety of other ions noteably calcium and magnesium which would interfere with conventional cation exchange resins should the Cr VI be reduced for capture by such resins.

DeVoe-Holbein composition DH-524 has been found to be exceptionally useful for the complete extraction of Cr VI from various waste waters, including those detailed in Table 6 (see Table 7). Very high extraction efficiencies and capacities

were found for this composition with these various waste waters. The composition was also found to be fully regenerable and result in small volumes of concentrated chromium waste. This chromium can either be returned for further use in the industry which generated it or it can be readily employed in secondary uses. The ceramics industry is an excellent example for secondary use. Chrome is a common colorant for glass and ceramics. DeVoe-Holbein has developed a technology employing chrome regenerant wastes and spent DH compositions where both are introduced into the ceramics industry as acceptable and useful raw materials. This closes the loop on both chrome waste and spent DH compositions, once they have served their useful lifetime of many regenerations.

Cesium and Strontium Recovery from Nuclear Wastes

Nuclear wastes consisting of various concentrations of metals at various radioactivities in water are generated both during the normal operation of nuclear power generating facilities and in the fabrication and reprocessing of nuclear fuels. Thus, various fission products including Cs and Sr are found in a range from relatively low amounts and activities in clean water systems used to store nuclear fuel to relatively high concentrations and activities in the wastes generated fron nuclear fuel reprocessing. Cs and Sr are considered important wastes from the points of view of their toxicities in biological systems and their long decay times. This has demanded safe long term storage forms for such wastes which can be met most effectively by concentration and containment. It has remained difficult to extract small but highly radioactive amounts of these metals from dilute wastes (e.g. fuel bay storage water) and to separate higher amounts of these when present in complex wastes containing a variety of other non-radioactive cations and anions at high concentrations (e.g. reprocessing wastes).

DeVoe-Holbein technology has been evaluated both in the laboratory and in the field for its ability to extract and concentrate Cs, Sr and Co from a variety of nuclear wastes. Table 8 details the analysis of two separate nuclear waste waters. Note the very low amounts of metal as radioactive Sr, Cs and Co in the waste water lagoon sample. However, significant radioactivity is associated with these metal contents. Extremely high capture efficiencies are necessary to remove these small amounts of metals.

DeVoe-Holbein composition DH-566 was found useful for the high efficiency extraction of Sr, Cs and Co from dilute wastes represented by the waste water lagoon and fuel bay storage/primary loop samples (Table 9). Substantial volume reduction factors were obtained by the column processing of these wastes with composition DH-566, while producing a treated waste effluent with no detectable amounts of ^{90}Sr, ^{137}Cs or ^{60}Co. The captured radioactive metal can be off-loaded in less than one bed volume of

[e] Volume Reduction Factor = Volume processed: Volume regenerant obtained for a single cycle of capture and regeneration.

regenerant or the loaded composition, due to its chemical nature, can be vitrified directly to produce a safe, imobile, long-term concentrated waste form (see below). This is highly desirable with waste such as ^{137}Cs and ^{90}Sr due to their long half-lives for decay (approx. 30 years).

Fuel reprocessing wastes containing very high amounts of the two major fission products ^{137}Cs (3.25 Ci/L) and ^{90}Sr (0.25 mCi/L) in the presence of large amounts of non-radioactive ions such as Na (30,000 ppm) have also been evaluated in the laboratory. This is accomplished by formulating samples with predominantly non radioactive Cs and Sr to avoid undue exposure to these isotopes. DeVoe-Holbein composition DH 566 has also been found useful in capturing Cs and Sr from such wastes. Capture efficiencies of approximately 99.9% and volume reduction factors of 10 have been achieved. This is highly significant due to the very high Na content of these wastes. This technology therefore appears to hold great promise for the concentration (volume reduction) and separation of highly radioactive ^{137}Cs and ^{90}Sr from such high level wastes.

Other Applications

DeVoe-Holbein technology has demonstrated its utility for the handling of a number of other waste streams not elaborated on in this report. Compositions have been found effective for the efficient capture of a variety of metals from plating and other waste streams including Cd, Zn, Cu, Ni, Co, Ag, Pb, U and Th. Some of these applications have been the subjects of other past (2) and upcoming (3) reports.

COMMERCIAL DEVELOPMENT OF DEVOE-HOLBEIN TECHNOLOGY

The DeVoe-Holbein technology, including the compositions, methods of use and regeneration, and a double encapsulation vitrification technology are protected by a number of pending patents throughout the world. DeVoe-Holbein International N.V. holds the world-wide rights to the technology and is commercializing various aspects of the technology through its various subsidiaries and joint ventures. Research and applications development are carried out at Laboratories in Dorval, Canada and Den Haag, Holland. North American Nuclear Corp. is commercializing nuclear applications in North America. DeVoe-Holbein/John Brown B.V., a joint venture company with John Brown Engineers and Constructors is commercializing certain aspects of the technology for the non-nuclear industries in both Europe and North America. DeVoe-Holbein International N.V. is working under an agreement with C. Itoh and Company of Japan in the commercialization of various aspects of the technology.

LIQUID-FILLED MEMBRANES

Liquid-filled membrane technology is not yet at a point where it can be applied on a commercial scale by any means, but it holds a significant potential for the removal of metals, particularly where selectivity is needed.

Several groups are actively engaged in research into liquid-filled membrane technology in the U.S.A., South Africa, and Israel. Although not yet applicable to acid mine drainage treatment, mention is made of the technology here to remind sponsors to keep an eye on this emerging technology.

Liquid-filled membranes work in much the same way as ion exchange resins in that metals are adsorbed from the liquid phase onto the membrane. The membrane may be an ion exchange type material similar to resins, or it may be a support for a solvent extraction organic phase, so membranes may function as solid/liquid or liquid/liquid ion exchange systems. The great advantage of liquid-filled membranes is that whereas the one side of the membrane is exposed to the feed pulp or solution, the other side may be exposed to the strip solution which continuously elutes the loaded resin membrane in the case of the liquid/solid IX mode and elutes the liquid film in the case of the liquid/liquid mode.

Because the adsorbant media is constantly being eluted, the loading on it never approaches equilibrium, and the adsorption system operates in a region where equilibrium favors adsorption even though there may be a high concentration of the recovered metal in the strip solution.

For normal IX and SX systems, several stages are needed to be able to bring the concentration of the adsorbed species down to a low level due to equilibrium considerations. Ion exchange resins loaded with metal values cannot remove metals from feed solution below a concentration that is in equilibrium with the partially loaded resin. That is, if resin loaded to [C]resin=A is brought into contact with a solution with concentration less than [C]solution=B, then metal will desorb from the resin to the solution and contactor concentrations of the metal ion in question cannot be reduced below B by that particular resin loaded to A.

CHELATION

Since in the liquid-filled membrane system metal values are constantly eluted from the system, adsorption in one contactor can proceed all the way down the equilibrium curve to very low concentrations.

Other advantages of liquid-filled membranes are:

1) Very expensive selective reagents can be applied in small amounts since extractant reagent consumption is said to be very low. This opens the way to using very selective crown-chelating ethers, for example.

2) In systems where the membranes are attached, a single contactor can be equivalent to an infinite number of stages where perfect mixing in each stage is assumed for conventional fluid bed IX systems.

3) Because metals are eluted at the same time as they are adsorbed, the size of the system can be reduced considerably. That is, a very much smaller surface area of membrane should do an equivalent job to that of a large amount of resin or organic phase SX.

Based on early testwork and IX theory, it has been found that adsorption at high concentrations is particle diffusion kinetics controlled and at low concentration ranges, it is film diffusion kinetics controlled. Consequently, whereas liquid-filled membranes should work very well at relatively high concentrations in the feed solution, very large surface areas are needed to achieve a reasonable transfer rate of metal ions from feed solution to the membrane.

Early tests on uranium and copper recovery by BEND RESEARCH of Bend, Oregon, for the U.S. Bureau of Mines demonstrated this fact when using sheet membrane surfaces. This led to the development of 0.025" i/d hollow membrane fibers which provide a larger surface area and in their case, a process for recovering hexavalent chromium from metal

finishing operations which is designed to treat more concentrated effluents which are reduced to 10-20 ppm Cr.

Research and development work into liquid-filled membranes is known to be undertaken by:

Polymeric Crown Ethers - Compounds

Dr. A. Warshawsky	Weizmann Institute Rehovot, Israel
Dr. Jorgenson	Brigham Young University Provo, Utah
Professor Marr	Technical University of Graz Graz, Austria
Professor Johan Smit	Dept. of Chemical Engineering Christian University of O.F.S. Potchefstroom, OFS South Africa

Liquid-filled Polymer Filament Modules -

Dr. Harold K. Londsdale Dave Kamperman	Bend Research, Inc. 64550 Research Road Bend, Oregon 97701 (503) 382-4100

The BEND RESEARCH filaments have a 0.025 inch inside diameter, and feed solution flows through the inside with stripping taking place on the outside. Modules are about 3 feet long and 5-6"Ø, and the system operates under a low pressure. The commercial units were still in the final stages of development as of January, 1985.

Plastic Membranes for Liquid-Filled Membranes -

Martin Hattingh, Managing Director

The Celgard membrane is designed to have up to 70% porosity, and most of the R&D work for development of a liquid-filled membrane process is being conducted in South Africa in conjunction with Professor Johan Smit of the Potchefstroom University.

It is emphasized again that liquid-filled membrane systems are not yet available on a commercial scale. Some workers in this field have indicated that crown-ether extractant liquid-filled membranes tested to date are relatively low flux units and, although very selective, have not been developed beyond an academically interesting phenomenon for that reason.

BIOLOGICAL OXIDATION FERROUS TO FERRIC

Biological oxidation of ferrous to ferric ions enabling iron to be precipitated as a hydroxide has been encountered as follows:

- Natural bogs in a West Virginia coalfield.
- The Portabog experiment by USBM.
- Suspended growth system of Thiobacillus Ferroxidans attached as a covering film to particulate bentonite.
- Use of rotating biological contactor-supported bacteria to convert Fe^{2+} to Fe^{3+}.

KLEINMANN, et al. (1983) described a portable bog experiment in which acid mine drainage was treated successively in five sections of loosely packed acid-conditioned sphagnum moss and one section of course limestone. The moss tolerated pH down to 2.3 and when the influent salt load decreased to less than 150 mg/l, the rate of acidity removal decreased. Apparently the portabog did not completely simulate results in a mature natural bog which has a deeper anaerobic zone.

KLEINMAN (1984 personal communication) showed slides of a natural bog containing sphagnum moss and cattails in West Virginia into which acid mine drainage from an adjacent coal spoil bank flows.

Within ten feet of the edge of the bog, the pH has increased to pH 4, and iron has precipitated and flocculated as ferric hydroxide. The mechanism for oxidation of the

ferrous ions and for the pH increase was not altogether explained. The USBM personnel are very interesting sources of information:

Patricia M. Erickson

THEIS, et al. (1982) described a method for oxidizing ferrous to ferric iron in acid mine drainage through the use of a suspended growth system of thiobacillus ferroxidans attached in a film to individual particles of bentonite and operated as a sequencing batch reactor. It was claimed that such biological oxidation followed by limestone neutralization is less expensive, safer, requires a lower pH, has a smaller solids buildup and avoids the danger of overtreatment while being very flexible.

Several experiments have been undertaken to oxidize ferrous ions in solution to ferric using bacteria attached to rotating biological contactors. It is believed that the HOMESTAKE MINING COMPANY has undertaken similar tests, but no published data was found. NOIKE, et al. (1983) examined bacterial activity in acid mine drainage containing 640 ppm Fe^{2+} and 4,500 mg/l SO_4^{2-}. It was found that acidophilic Fe oxidizing bacteria from the receiving waters have the greatest activity at about 30°C and pH 2.

The rate of oxidation of Fe^{2+} increases exponentially between 20°C and 30°C as retention time increases, and the activity of the acidophilic Fe-oxidizing bacteria decreases greatly at ten degrees. The number of bacteria attached to the surface of a rotating biological disc was found to increase as the ferrous Fe loading increases.

A considerable amount of work has been undertaken by the Pennsylvania State University on the use of rotating biological contactors for the treatment of acid mine drainage.

UNZ and WICHLACZ (1982) determined that transformation of Fe^{2+} in rotating biological contactors for the partial treatment of acidic coal mine drainage is capable of achieving Fe^{2+} oxidation efficiencies of 90% while sustaining a resilient population of chemolithotrophs over a wide range of temperature, pH, and mass Fe^{2+} loadings. Performance of the system was shown not to be adversely affected by sudden alterations of abiotic variables over the range typical in the natural environment. It was found that the microbial composition of the mine drainage environment consists of diverse acidophilic chemo-organotrophic bacteria in addition to the chemolithotrophs. Interrelations which may exist between the two microbial groups need to be identified to exclude the possibility that combined heterotrophic-autotrophic activities are the major biological force in the generation of acidic mine drainage.

Earlier work by Pennsylvania State University was described by OLEM and UNZ (1980, 1980A) in which a prototype rotating biological contactor was evaluated under conditions simulating actual treatment of acid mine drainage. Under all conditions, continuous microbiological oxidation of Fe^{2+} to Fe^{3+} occurred. At mine water temperature as low as 0.4°C, Fe^{2+} was found to occur albeit at a reduced rate.

Pilot scale (0.5 m diameter) and a prototype (2 m diameter) RBC's were investigated as a means of oxidizing ferrous ions in six heterogeneous mine waters at three coal mines in Pennsylvania and West Virginia. Continuous biological oxidation of ferrous ions was achieved at natural mine temperatures ranging from 0.4°C at Hawk Run, Pennsylvania, to 29°C at Crown, West Virginia. At 0.4°C, the oxidation rate of Fe^{2+} was 10-20% of that achieved at 10°C. At 10-29°C, oxidation efficiency of Fe^{2+} was about 80%. At Crown, West Virginia, the oxidation of Fe^{2+} with the 0.5 m RBC was unaffected by influent pH values in the range 2.18-5.50.

Fe^{2+} oxidation was, on average, 10% less efficient for a minewater treated under similar operating conditions with the 2.0 m RBC than with the 0.5 m RBC.

Neutralization of RBC effluent and separation of precipitated iron sludges is necessary to produce water of suitable quality to be discharged to a stream. Both Fe oxidizing and heterothrophic bacteria existed in a gelatinous matrix on the RBC disc surfaces which were operated at a test site at Hollywood, Pennsylvania.

In general RBC's are applicable where:

1) The organism grows on a fixed media.

2) The organism can slough from the media after it completes its life cycle.

Walker Process supplies test units in two sizes:

- 6'Ø media with 4 modules, each 3' wide with a total of 22,000 ft^2 constructed in a steel tank which hooks up for inflow and outflow.

- A 3'Ø media unit which is 2' wide for bench scale pilot testing.

UNZ, et al. (1979) reported that supplementation of a synthetic feed solution with acid mine drainage water enhanced the oxidation of Fe^{2+} by Thiobacillus ferrooxidans in small scale RBC's, although the active ingredient was not known. At temperatures much below 10°C, the oxidation rate was reduced substantially, but at 25°C, the oxidation was not much different from that at the 10°C control. In the pH range 2.2-5.2, efficiencies were usually over 80%.

BIOLOGICAL SULFATE REMOVAL

Biological oxidation of thiosulfate has been attempted at NEW BRUNSWICK MINING AND SMELTING near Bathurst, N.B., in Canada. These experiments with activated sludge and pebble beds are reported not to have indicated an economically attractive or practical process for this particular case. The aim at Brunswick Mining was to oxidize thiosulfate so that the acid generated could be neutralized before the effluent leaves the property, rather than sulfate removal.

Sulfate removal may become necessary to meet effluent discharge regulations in some parts of the U.S.A. where 250 ppm $SO_4^=$ has been included in proposed effluent discharge regulations. The motivation for such a low level is not known, but such a proposed standard is referred to by HOLM and SIMPSON (1981). In South Africa on the Witwatersrand, regulations are being considered which will limit point source discharge TDS levels, possibly at 250 mS/m which is around 2000 ppm TDS. Sulfate forms a significant part of the TDS load of such effluents even after neutralization.

The possibility of removing sulfate biologically is worth further investigation because the alternative--desalination by reverse osmosis and evaporation or electrodialysis--is relatively capital and operating cost intensive.

The reduction of sulphates in natural waters through the agency of filamentous algae attached to rocks and pebbles is well established and was in fact the subject of a presentation to the French Academy of Sciences by M. E. Plauchud. Living filamentous algae in the presence of calcium sulfate yield H_2S.

Since 1886, it has been known that bacterial action produces H_2S from sulfates, or, in the presence of gypsum, iron oxide and a source of carbon, the products are likely to be $CaCO_3$, FeS, CO_2, and CH_4. Experimental results to this effect were reported by F. HOPPE-SEYLER (1887).

In 1882, ETARD and OLIVER found that some bacteria, the Begiattoa which are common in lakes and the sea, especially around sulfurous waters, contain sulfur granules in their protoplasm. When the same bacteria are grown in solutions free from sulfates, the sulfur granules disapeared, forming again when the bacteria were grown in a solution of calcium sulfate.

Filamentous blue algae of the genus Oscillaria and green algae of the genus Ulothrix were also found to decompose sodium and calcium sulfates with formation of sulfur and hydrogen sulfide.

The Dutch bacteriologist, W. M. BEYERINCK (1895), recognized the very considerable importance in nature of bacterial reduction of sulfates which he correctly suggested was

the cause of the high H_2S content of Black Sea water. He also predicted that the absence or extremely low levels of sulfates in the deeper layers of soil in certain parts of Holland was due to sulfate-reducing bacteria which has also subsequently been verified.

BEYERINCK isolated an organism, Spirillum desulfuricans, which has since been named Microspira desulfuricans which rapidly reduces sulfates under anaerobic conditions to H_2S.

As a result of bacterial reduction of sulfate in the salt water canals of the Dutch coastal tract, this water is often high in H_2S, and the canal bottoms are often coated with muds which, to a thickness of many meters, are blackened by iron sulfide with only a few mm of light-colored muds overlying the black mud. VAN DELDEN (1903-1904) ascribed the H_2S generation to an organism which he named Microspira aestuarii.

M. desulfuricans is intolerant of salt water, and M. aestuarii is intolerant of fresh water although both are tolerant of brackish water to 1.5% NaCl. Both are strictly anaerobic, and the presence of organic food in the culture media is essential for sulfate reduction.

Optimum temperature for the growth of M. aestuarii is 25-30°C. The organism will take oxygen from not only sulfates, but also sulfites, thiosulfates, and to a limited extent from nitrates. Where oxygen was present, sulfur was found due to the decomposition of H_2S. $2H_2S + O_2 = 2H_2O + 2S$.

ELION (1924-1925) discovered another bacterium named Vibrio thermosulfuricans that flourishes best at 55°C and appears to grow more rapidly than Microspira desulfuricans and M. aestuarii. Growth rate diminishes both above and below the optimal temperature. Media innoculated with Vibrio thermo-sulfuricans showed profuse growths overnight. Sulfate reducing bacteria have been found in river muds, brackish canal muds, sewage, soils, lake sands, dune sands at depths to 37 m, black muds of the ocean bottom to depths of 16 fathoms, and bottom muds of the Black Sea to depths of 2,118 m where conditions are highly anaerobic with pressures as high as 3,000 psi.

According to tests by ALLEN, CRENSHAW and JOHNSON (1912), when copper sulfate is present with calcium sulfate, the possibility of bacterial action is eliminated through the creation of aseptic conditions. The level of copper that can be tolerated was not quantitatively established.

The above details were extracted from a summary by BASTIN (1920's) and clearly indicates that several bacteria reduce sulfates and, depending on conditions, yield $CaCO_3$, H_2S, and CH_4 or $CaCO_3$, H_2O, S, and CH_4. This phenomenon is potentially useful in the removal of sulfates from solutions or in precipitating heavy metals in polishing ponds.

STARKEY (1956) pointed out that inorganic sulfur compounds including H_2S, $S_2O_3^{=}$, polythionates, $SO_3^{=}$, and elemental S are produced by micro-organisms in the aerobic and anaerobic transformation of organic and inorganic compounds of sulfur or reach waters in waste materials. These can be oxidized by three groups of autotrophic bacteria, namely photosynthetic sulfur bacteria, colorless sulfur bacteria with large cells sometimes producing filaments and colorless bacteria of the genus Thiobacillus. Various heterotrophic microorganisms including bacteria, aclinomycetes, and filamentous fungi also oxidize some of the sulfur materials. Each of these mechanisms is described, but the important aspect is that whereas some bacteria reduce sulfates, other microorganisms can reverse the reactions.

STARKEY (1956) mentions several additional bacteria that reduce sulfate or incompletely reduced sulfur compounds such as sulfite, thiosulfite, tetrathionate, and elemental sulfur; for example, the genus Pseudomonas was found to reduce thiosulfate to sulfide. He suggests that the most important sulfate reduction process is that affected by the specific sulfate-reducing bacteria known as genus Desulfovibrio, the most common of which is referred to as Desulfovibrio desulfuricans.

Sulfate-reducing bacteria are strictly anaerobic and use the sulfate as the hydrogen acceptor, and sulfite, thiosulfate, and tetrathionate can be used in place of sulfate. Various organic materials can be used as hydrogen donors including organic acids, alcohols, amino acids, and carbohydrates, following the typical reactions:

$$2\ CH_3\ CHOHONa + MgSO_4 = 2\ CH_3\ COONa + H_2S + CO_2 + MgCO_3 + H_2O$$

$$4H_2 + CaSO_4 = H_2S + Ca(OH)_2 + 2H_2O$$

The sulfate reducing bacteria have been implicated in anaerobic corrosion of iron and steel. This corrosion is rapid and is not self-stifling as is rusting where the adherent oxide film protects the underlying metal. Sulfide coating of the metals (or concrete) are then attacked by bacteria such as Thiobacillus ferroxidans or Thiobacillus sulfoxidans which generate relatively concentrated sulfuric acid at the localized surface which corrodes the metal or concrete surface. An example of where this is observed is described in the trip report on the ROSSING URANIUM MINE in Namibia where corrosion is associated with jarosite scale in pipelines carrying sulfate-rich reclaimed tailings solution.

WAKAO, et al. (1979) tested sulfate reducing bacteria in a mixed bacterial population as a means of removing $SO_4^{=}$ from acid minewaters from the abandoned Matsuo Sulfur and Pyrite Mine in Iwate Prefecture, Japan. Batch and continuous flow systems were tested using sawdust as the basic culture medium. Vigorous $SO_4^{=}$ reduction and neutralization of the acid mine water occurred in the batch cultures supplemented with organic nutrients peptones, Na-formeate, Na-lactate, or Na-pyruviate. SO_4 reduction worked only above

pH 4 and was tested in the range 4-5.2. pH seems to have been increased through the activity of other heterotrophic microflora. Neutralization of the acid mine water to pH 4 by SO_4-reduction was possible in the continuous flow system if organic nutrients usable by the bacteria were supplemented and the flow rate of the effluent property controlled.

Although the organic nutrients selected and the use of sawdust as a growth medium does not appear very practical for large-scale commercial applications, WAKAO, et al. (1979) have demonstrated that, in principle, biological processes have a potential application in the removal of sulfates from acid mine drainage. More information has been requested from:

DR. NORIO WAKAO

Awate University
Morioko 020 Japan

Given the recent extension in application of biological processes for the treatment of mine and mill effluents, it is believed that bacterial processes hold significant potential for reducing sulfate levels from neutralized AMD. It is emphasized that this is still in the concept stage with no practical cases known to date.

BRIERLEY and BRIERLEY (1981) refer to sulfate reducing bacteria Desulfovibrio and/or Desulfotomaculum being present in minewater ponds at a uranium mine in New Mexico and found that these may have a role in the removal of uranium, selenium, and possibly molybdenum from solution.

SPISAK (1979) saw metallurgical effluents of the nonferrous industries to represent a growing challenge to microbiological research. New environmental protection effluent discharge limits cannot be met by conventional chemical treatment, and he regards biochemical approaches as being one of the few methods that may be able to achieve the emerging objectives, especially for removing arsenic, for example, from smelter scrubber bleed solutions.

Sulfur compound removal was identified by SPISAK (1979) as being complex and important, particularly for copper smelter-refineries from which "a plethora of sulfur problems" in the form of sulfur dioxide, acidic tailings streams, sulfate saturated effluents, and sulfate containing dusts combine to create some serious environmental compliance barriers. These streams are often highly acidic at pH 1.0-2.0 in acid mine drainage, for example, and at pH 9-10.0 in ammonia-type hydrometallurgical process discharge streams from solvent extraction. He refers to work at the University of Arizona by CORK and CUSANOVICH (1978) which indicated a mutualistic relationship between Desulfavibrio desulfuricans and Chlorobium thiosulfatophilum in which sulfate is reduced to sulfide and subsequently re-oxidized to elemental sulfur. The sulfate source in this work was a solvent extraction raffinate derived from an oxidative ammonia leach

process employed by THE ANACONDA CO. for the processing of copper sulfide concentrates. Conventional treatment of this ammonium sulfate is to add calcium hydroxide and live steam for the purpose of recovering ammonia and fixing the sulfate as gypsum. This method does not address the problem of eventual disposal of the low-grade gypsum product.

A bacterial system that combines sulfate treatment and the production of potentially valuable by-product sulfur could be of significant advantage, but the inherent complexity of a mutualistic bacterial system was considered to be a potential stumbling block for a commercial process.

Some of the potential economic problems arising from the work of CORK and CUSANOVICH (1978) include the dependency of Desulfovibrio desulfuricans on sodium lactate as a reductant source. Although the bacteria efficiently reduce $SO_4^{=}$ to H_2S rapidly, the use of lactate as a substrate would be prohibitively expensive.

Sewage or pulp wastes could be employed as carbon sources, but problems would arise concerning additional impurities and rate considerations.

Oxidation of H_2S to elemental sulfur by Chlorobium thiosulfatophilum is not difficult because these bacteria are photosynthetic, and they excaete sulfur outside the cell. The use of cell culture to produce a final product, sulfur, presents complex problems of physical separation which add both cost and complexity to any proposed treatment scheme.

SPISAK (1979) shows a schematic representation of a bio-process for sulfur based partially on the work of CORK and CUSANOVICH (1978).

FIG. 3. Bio-Process sulfur recovery.

A sulfate effluent stream is slowly fed to a series of reduction reactors containing Desulfovibrio desulfuricans. An inert purge gas carries away H_2S generated to a series of photosynthetic reactors where Chlorobuim thiosulfatophilum generate elemental sulfur. The remaining sulfide gas proceeds to a metal sulfate scrubber where its discharge would be transported to a conventional metallurgical process.

Settled residues from the sulfide oxidation vessels would be continuously bled to a filter where the bacterial matter and sulfur would be separated from the media solution. This solid material then reports to a heat exchanger under inert atmosphere, and the sulfur is melted and filtered away from the biomass. The cooled filtrate is the final sulfur product while the biomass goes on to a digester for nutrient recycle. Additionally, a continuous bleed of cells from the oxidation reactors is maintained in order to hold a stable population in the reactors. These cells would be moved to digesters while the media would be enriched and recycled.

Likewise, a continuous bleed of cells and metal precipitates would be drawn from the sulfate reduction reactors and partially dewatered. The resultant solids would undergo conventional hydrometallurgical flotation in which metal sulfides are treated with surfactants and, using air sparging, are floated from the rest of the residue. These metal sulfides would then be dewatered and transported to a conventional metallurgical process while the remaining bacteria are sent to digestion for media enrichment. The products of these several stages of biomass digestion must be acceptable as nutrients to the Desulfovibrio reactors or the economic advantages of such a flowsheet would be lost.

From the above concept description, it is clear that the sulfur recovery flowsheet would be relatively complex and expensive but would yield a valuable by-product while recycling most of the needed energy internally. Considerable R&D and pilot scale development work would be needed to make this process suitable for consideration on a commercial scale. SPISAK (1979) has succeeded in demonstrating the technical potential for such a process within a metallurgical environment.

BIOLOGICAL METAL REMOVAL PROCESS

Biological metal removing processes involving plants, algae, and/or bacteria have already been discussed in connection with passive AM[illegible]ment or polishing.

This method represents a significant potential horizon but requires significant further research and development.

ALGAE

SHERRITT and LESTER (1979) reviewed the removal of heavy metals and neutralization of acids in mine wastewater by algae and bacteria.

Several successful projects have been undertaken to remove metals and organics in polishing ponds as described above under passive treatment systems, and it is believed that a new biological polishing pond is to be installed at RIO TINTO ZINC's zinc refinery at Avenmouth, England.

A summary of this work is provided by GALE and WIXSON (1979).

It is important to regard bogs and marshes as an ecological system consisting of plants, algae, and bacteria, all of which can be used to advantage. Multidisciplined knowledge is needed to define all the parameters to allow such systems to be optimized and engineered. It is important to determine the effect of an algae or plant on direct metal removal, but it is more important to understand the net ecological effect including putrification of dead biomass, bacterial processes, etc. in the complete ecosystem.

JENNETT, SMITH, and HASSETT (1983) presented a summary of "Factors Influencing Metal Accumulation by Algae." This review refers mainly to studies around the New Lead Belt of Missouri which has been the subject of intense study.

JENNETT, et al. (1983) seeked laboratory-derived information on the factors influencing heavy metal accumulation by algae which is only one side of the coin, albeit an important

one. An interesting observation is that most of the metal removed by algae can be recovered by a rinse with 0.01 M EDTA or 0.1 N HNO_3 which suggests that surface adsorption is the principle mechanism for removal of metals by algae from an effluent stream. Also, the ability of algae to remove metals was found to be generally in the following order starting with the highest to the lowest: mercury, lead, cadmium. Neither zinc nor arsenic was significantly removed at any pH by the algae during a three-hour exposure.

The authors of this paper on algae accumulation of metals all work at Syracuse University, New York.

Russian investigators, KOVAL'SKIY and VOROTNITSKAYA (1965), reported that algae are involved in the translocation of uranium in a lacustrine environment. The alga, Chara, could concentrate uranium in lakewater up to 1,000 times. Uranium in the Chara eventually passes to the lake muds since uranium concentrations in the mud correlated directly with the amounts of the element associated with the Chara. Chara is a calcareous algae and is encrusted with crystalline hydrous carbonates. It is possible that uranium associated with Chara may be liebergite $Ca_2UO_2(CO_3)_3\ 9H_2O$ according to KOVAL'SKIY and VORATNITSKAYA (1965). Chara has been attributed to removal of uranium from minewater by BRIERLEY, et al. (1980).

BRIERLEY and BRIERLEY (1981) concluded, however, on the basis of a four-year study on site at a treatment facility for minewater from two mines, No. 35 and No. 36 of Kerr McGee Nuclear Corp. at Ambrosia Lake near Grants, New Mexico, that:

1) The concentrations of soluble uranium, selenium, and molybdenum were not diminished in minewaters by passage through the series of impoundments which constituted the minewater treatment facility. Uranium concentrations were reduced, but this was due to the passage of the water through an ion exchange column.

2) Particulate concentrations of the minewater were reduced at least ten-fold by passage of the waters through the impoundments. Since uranium, selenium, and molybdenum were associated with suspended particles, reduction in the concentration of total suspended solids reduced the concentration in the final effluent.

3) The ponds were well oxygenated. This was probably due to their shallow depth and the growth of algae.

4) The pH remained near neutral during all collections which would indicate that the major soluble species would be molybdate, uranyl carbonate, and selenite (and possibly selenate at higher pH values).

5) Temperature remained above 10°C in winter suggesting that plant and microbial life could remain active even in winter because the volume of water was large enough to lessen large temperature fluctuations.

6) Phosphate and nitrate were present in high enough concentrations to support limited algal and microbial activity.

7) Sediments were anonic and enriched in uranium, molybdenum, and selenium. The deposition of particulates and the formation of insoluble compounds were proposed as mechanisms for sediment enrichment.

8) The predominant algae of the treatment ponds were the filamentous Spirogyra and Oscillatorea and the benthic alga, Chara.

9) Adsorptive processes resulted in the accumulation of metals in the algae cells.

10) Laboratory study indicated that Spirogyra was more active than Chara in the removal of uranium and molybdenum from solution.

11) The algae appeared to act as bio-filters for accumulation of particulate pollutants in the ponds.

12) The retention of uranium and molybdenum in sediments following the death and decay of the algae was dependent on the maintenance of reducing conditions.

13) The pond sediments had large numbers of sulfate-reducing bacteria Desulfovibrio and/or Desulfotomaculum.

14) Stimulation of sulfate reduction by the bacteria resulted in retention of molybdenum, selenium, and uranium in sediments.

15) Estimation of algae productivity and removal of uranium and molybdenum by the algae indicated that both stimulation of algal productivity and the increase in pond size are necessary for the system to be effective in the removal of trace contaminants.

16) Anaerobic biological reactors show promise for use in the removal of U, Se, and other pollutants in uranium mine wastewater.

17) Studies must be continued to optimize biological reactor column design and nutrient source.

The BRIERLEY and BRIERLEY (1981) report contains an excellent description of relevant chemistries of uranium, molybdenum, and selenium and of literature searches of biological mechanisms for the removal of these metals.

In 1984, testwork in the propagation and use of benthic alga Chara for removal of metal contaminants including uranium was started in the Elliot Lake district at RIO ALGOM LTD. and DENISON MINES LTD. This work is being undertaken by:

CHAROPHYCEAE

WATER HYACINTHS

NATH (1982) included a mention of the usefulness of the water hyacinth in treatment wastewaters in tropical or warm temperate climates. This plant does not grow in water that is 50°F or colder; their optimum growth temperature being 70 to 86°F. The water hyacinth selectively filters out heavy metals (Cd, Hg, Ni, Pb, and Ag) and can adsorb and metabolize nutrients in sewage effluents according to WALTERS (1976), MIDDLEBROOKS and REED (1981), and PARKINSON (1981).

In sewage treatment water, hyacinths have been harvested for use in methane generation and as feed rations for beef cattle. The economics of harvesting this aquatic plant were

not yet resolved in 1982, and plants harvested from industrial wastewater treatment lagoons cannot be processed into animal feed because of the presence of toxic metals.

SPISAK (1979) referred to a common New Zealand lake weed, Ceratophyllum, which is effective in arsenic removal from effluents which would be dried and ashed. It is reported by CHAPMAN, et al. (1974) that certain algae indigenous in some New Zealand Lakes can contain up to 2% arsenic of their dry weight. These organisms, Ceratophyllum demursum and Largosiphon major, are capable of assimilating large amounts of arsenic and continuing to grow.

The rate of arsenic uptake by these weeds is phenomenal. In a series of experiments designed to kill off fouling algae in New Zealand, arsenic salts were dumped into a Waikato river-fed lake to a concentration of 5 mg/l. The rate of algal assimilation reduced the quantity of arsenic present in the water by 80% per day according to FISH (1963) until a stable concentration of 6 micrograms/l was achieved. Application of this assimilation rate to a copper smelter effluent containing 1 mg As/l would achieve 40 micrograms/l in a two-day period.

SPISAK (1979) proposed a supplemental arsenic scrub circuit for treatment of scrubber bleed streams which consists of a series of high surface area to volume ratio, light penetrable reactors to accept the arsenic bearing effluent. The reactors would contain a 5% by weight algal solution where a total system of water plus algae would consist of 26,000 kg. The 5% wet weight fraction of algae would represent 1,300 kg of plants which would be capable of assimilating a total of 2.6 kg of arsenic. With an effluent feed at 300 l/min at 1 mg As/l at neutral pH, and assuming 1 g arsenic assimilation per 100 dry grams algae per day, approximately 430 kg algae must be harvested per day to balance the daily imput of 0.43 kg arsenic per day. A daily harvest of 430 kg would remove all the influent arsenic and allow for a 50% plant mass regeneration per day.

The two photosynthetic reactor vessels containing a total of 1,300 kg of algal plants in 24,700 kg water would constitute the arsenic assimilation phase of the process.

The daily 430 kg biomass bleed would be filtered on a drum filter for dewatering. The filtered liquor would proceed to a small mixup vessel where growth nutrients would be replenished and recycled to the reactors. The filtered algae would proceed to a drying pad, and the dried biomass then incinerated in air at a temperature exceeding 300°C to

insure vaporization of the As_2O_3. Hot gases would pass through the heat exchanger of a waste heat boiler for energy recovery and then, carrying the condensed arsenic would proceed to a Kosaka-type dust treatment process thus closing the loop as illustrated. This discharge liquor from the algal reactors would average 40 ppb arsenic/l and would therefore be suitable for discharge.

Supplemental arsenic scrub circuit for treatment of a Kosaka-type effluent.

SOURCE: SPISAK (1979)

SPISAK (1979) provided an equipment list and a capital and operating cost estimate for the arsenic removal system which for a plant producing 60 metric tons of copper per day. He worked out a cost of U.S. ¢0.09/lb Cu produced, and capital costs in 1978 were around $834,000.

BACTERIA

Numerous accounts of metal removal through bacterial action have been noted in nature, and several attempts to create economically attractive processes for the treatment of mine and mill effluents have been made.

MUDDER and WHITLOCK (1984) and WHITLOCK and MUDDER (1984) describe pilot plant tests and a large commercial scale bacterial treatment of a mine and mill effluent at HOMESTAKE MINING COMPANY's gold recovery operations at Lead, South Dakota. This is the first known use of bacterial treatment for mine and mill effluent treatment. Although designed primarily around the removal of cyanide, thiocyanate, and ammonia, other metals including copper, arsenic, and gold are removed from solution. In this case, nutrients are added to the effluent stream which is treated using rotating biological contactor supported bacteria--Pseudomonas paucimobilis. More information on the practical

aspects of operating this plant are likely to emerge in the near future, and some additional detail is provided from published sources in Appendix I.

A process, AMT-Bioclaim, has been developed based on a biological phenomenon for the recovery of metals from dilute concentration wastewaters containing between 10 mg/l-100 mg/l metal. The system is primarily effective in the recovery of cationic species such as silver, lead, copper, and other common metals although cyanide complexed gold and silver can be accumulated in the process. Rapid recovery of metals is achieved over broad pH and temperature ranges. Recovery is little affected by the presence of many organic or inorganic metal complexing compounds. The process is designed for use in standard equipment designed for water treatment and metals recovery such as column and counter current pulsed bed reactors. Metals can be recovered from wastewaters generated from manufacturing industries, and the recovery of gold from leach solutions may also be possible. Following metal removal from solution, the metals can be recovered by a proprietory process with recycle of the metal-sorption agent.

BRIERLEY, BRIERLEY, and DREHER (1980) discuss several bacterial and algal phenomena in a series of ponds used to treat minewater from uranium mines at Ambrosia Lake near Grants, New Mixico. Sulfate reducing bacteria of the genera Desulfovibrio and Desulfotomaculum remove uranium, molybdenum, and selenium in various ways which accumulate in the pond sediment. Sulfide generation precipitated molybdenum and selenium whereas uranium is precipitated through a reducing effect. Filamentoris spirogyra and benethic Chara are predominant among the algae in the ponds, and the first was found to be more active than the latter in the removal of uranium and molybdenum. The algae appear to act as biofilters for accumulation of particulate pollutants and agents for adsorption and/or absorption of soluble pollutants. Additional

information may be available from Jim W. Kauffman, Kerr McGee Technical Center, Oklahoma City, or from Jim Cleveland, QUIVIRA MINING COMPANY, Grants, NM, 87020, (505) 287-8851.

REMOVAL OF SELECTED INORGANIC POLLUTANTS FROM URANIUM MINE WASTE WATER BY BIOLOGICAL METHODS

J.A. Brierley, C.L. Brierley, and K.T. Dreher

Department of Biology, and New Mexico Bureau of Mines and Mineral Resources, New Mexico Institute of Mining and Technology, Socorro, NM USA

ABSTRACT

Water from underground uranium mines located in the Ambrosia Lake district near Grants, New Mexico, U.S.A., is treated to reduce levels of uranium, selenium, radium and molybdenum. The treatment system consists of a series of ponds and an ion exchange plant. Bacterial and algal populations present in the pond system are considered agents which actively assist in removal of the pollutants present in the water. Pond-bottom sediments maintain a reducing zone and a large population of sulfate-reducing bacteria of the genera Desulfovibrio and Desulfotomaculum. Uranium, molybdenum, and selenium accumulate in the pond sediment. Stimulation of the microbial sulfate-reducing activity resulted in a decrease of soluble concentrations of these elements in laboratory systems. Predominant components of the treatment ponds' algal flora are the filamentous Spirogyra and benthic Chara. Laboratory study indicates that Spirogyra is more active than Chara in removal of uranium and molybdenum from solution. However field-collected algal samples of both of the genera contain uranium and molybdenum. Laboratory studies indicate that death and decay of the algae in association with pond sediment does not result in return of cell-bound uranium and molybdenum to the water. The algae appear to act as bio-filters for accumulation of particulate pollutants and agents for adsorption and/or absorption of soluble pollutants

INTRODUCTION

The mining of uranium ore may produce water from de-watering operations containing dilute concentrations of uranium, molybdenum, selenium, radium and other associated ions. This water presents a waste disposal problem, as the contaminants must be removed before the water can be discharged from a mining property. In addition, it is a potentially valuable source of economically important elements. Reclamation of mine wastewater can serve two purposes: removal of potential pollutants and concentration of resources. Several processes are available for soluble ion concentration including precipitation, ion exchange, solvent extraction and electrowinning. However, these systems are quite often ion specific and expensive when treating large volumes of water. An alternative system for resources concentration is based upon biological processes. Such a system has the potential for low cost, ion non-speci-

fic activity and efficiency in dealing with dilute solutions.

Microorganisms are effective agents in concentration of metals from solutions (see Kelly, Norris, and Brierley, 1979, a recent review of the topic). Norris and Kelly (1979) found yeasts to be more efficient than bacteria in gross removal and accumulation of nickel and copper. Bacteria will concentrate potassium, magnesium, manganese, iron and calcium (Eisenstadt, et al., 1973), and also produce complexing agents which selectively extract metals from dilute solution (Pollack, et al., 1970). There appear to be two mechanisms by which microbes concentrate metals: binding of metals to cell surface components and metabolism dependent intracellular accumulation (Gadd and Griffiths, 1978). Hatch and Menawat (1979) reported that the bacterium Sphaerotilus natans, found in waste sludges and polluted waters, will accumulate iron, magnesium, copper, cobalt, and cadmium in an external mucilage layer. The accumulation was a mass transfer limited process. Other physiological activities requiring metabolically active cells also lead to insolubilization. Uranium (VI) was reduced by cell extracts of Micrococcus lactilyticus using hydrogen as an electron donor. The extract could also reduce molybdate to molybdenum blues and selenium to selenate (Woolfolk and Whiteley, 1962). As microbes accumulate heavy metals, it is of concern whether these metals are released upon death and cellular lysis. Guthrie and Cherry (1979) found that accumulated heavy metals increase in sediments as the organisms die, but some of metals are returned to a system in organic detritus.

Systems utilizing bacteria or fungi have been proposed for removal of uranium from wastewater (Shumate et al., 1978; Shumate et al., 1979; Volesky and Tsezos, 1979). These processes were based upon biosorption using cell masses of the respective microbes. The fungus Rhizopus arrhizus accumulated 185 mg uranium per gram dry weight of cells (Volesky and Tsezos, 1979). A mixed culture of denitrifying bacteria decreased uranium in solution from 25 g/m^3 to 0.5 g/m^3 in just 8 minutes while accumulating 0.14 g uranium per gram of dry cells.

Algae have also been found active in biosorption of pollutants from aqueous solution. Marine algae growing near tailings of an iron ore mine concentrated iron, manganese, lead and zinc on cell-wall material (Wong et al., 1979). Marine algae also accumulate uranium, plutonium and polonium (Hodge et al., 1979). The algae collected the particulate form of the radioelements by an organic coating on their cell surface. Filip et al. (1979) used semi-continuous cultures and mixed algal flora (Chlorella, Scenedesmus, and Oscillatoria), for heavy metal removal from wastewater. The algae absorbed 70 to 90% of the cadmium and copper and 20% of the chromium; but the amount of chromium removed was substantial, as the chromium concentration in solution was high (250 g/m^3). However, cadmium and copper were released from algae after cell death. Gale and Wixson (1979) utilized algae to reduce the amount of particulate matter and heavy metals (e.g., lead, zinc, copper and manganese) in lead mining and milling effluents. A system using several types of microbes was proposed for heavy metal removal from lakes and streams polluted by mine and smelter wastes (Jackson, 1978). Algae may function in heavy metal accumulation and transport to bottom sediments. The metals can then be sequestered as metallic sulfides by bacterially produced hydrogen sulfide. In addition, the algae provide the organic substrate necessary for sulfate reduction by the bacteria.

The sulfate-reducing bacteria, Desulfovibrio and Desulfotomaculum, precipitate copper and mercury from dilute solutions (Ehrlich and Fox, 1967; Ilyaletdinov et al., 1977; Temple, 1964; Temple and LeRoux, 1964; Vosjan and Van Der Hoek, 1972).

Dockins et al. (1980) suggested that Desulfovibrio be used to control mining related pollution problems. It has been proposed that Desulfovibrio could be involved in deposition of uranium from solution (Jensen, 1958). The hydrogen sulfide produced by the bacteria reduces uranyl ion to uraninite. According to Taylor (1979), uranium enrichment is likely to be enhanced where reducing conditions occur in contact with water in which oxidizing conditions prevail (i.e., sediment-water interface).

The Kerr McGee Corporation has a treatment process for waste-water from two uranium mines in the Ambrosia Lake district near Grants, New Mexico, U.S.A. The system consists of several settling and algae ponds. The pond sediments concentrate uranium (1037 g/m^3), selenium (30 g/m^3), and molybdenum (160 g/m^3). The system has been effective in reducing the concentions in the water of the uranium (from 5.8 to 0.8 g/m^3), selenium (from 0.03 to 0.01 g/m^3), and molybdenum (from 2.3 to 0.8 g/m^3) (Brierley and Brierley, in press). This system is being evaluated to identify the biological agents which participate in removal of the pollutants and to determine the mechanisms which operate. The data reported in this paper represent a portion of the study.

MATERIALS AND METHODS

Field Site

The wastewater treatment system has been described previously (Brierley and Brierley, in press). The mine water passes through a series of settling ponds, and water from one mine is also treated with an ion exchange resin to remove uranium. Barium chloride is added for radium removal. The combined mine waters subsequently flow through three consecutive algae ponds prior to discharge.

Analyses

Uranium concentrations were determined by the TOPO procedure (Johnson and Florence, 1971). Molybdenum was quantitated by the method of Meglen and Glaze (1973).

Algology

Algae samples were collected in nonsterile polyethylene bottles and placed on ice for transport to the laboratory. The samples were either dried for metal analyses or transferred to $2.0 \times 10^{-2} m^3$ aquaria for laboratory culture. Shen's Medium (Shen, 1971), was used for algae culture. Algae populations were identified using the keys of Prescott (1954) and Smith (1950).

Removal of molybdenum and uranium from solution by algae was tested in short-term uptake experiments. Using 250-ml erlenmeyer flasks, 100 ml Shen's Medium at pH 7.8 were spiked with 2 g/m^3 molybdenum (added as $Na_2MoO_4 \cdot 2H_2O$) and 10 g/m^3 uranium (added as $UO_2SO_4 \cdot 3H_2O$). Duplicate flasks contained 1 g wet weight algal material either as whole cells or as particulate material produced by disintegrating the cells one minute in a Sorvall Omni-Mixer (Ferguson and Bubela, 1974). Flasks were incubated 24 hr in light before samples were collected by filtration through 0.4 µm "Millipore" filters and acidified with 1.5% (v/v) HNO_3.

Long-term interactions between water, algae and sediment were modeled in the laboratory using $2.0 \times 10^{-3} m^3$ growth tanks. An initial aliquot of 5 g wet weight algae was grown in $1 \times 10^{-3} m^3$ Shen's Medium spiked with 2 g/m^3 molybdenum and 5 g/m^3 uranium. After 13 days' incubation in light, containers were placed in the dark to promote decay of the algae. At that time, 150 g pond sediment were added to two containers of each algae and to two control containers without algae. Removal of metals was monitered by periodic sampling of the nutrient medium only, medium plus sediment, algae only, and algae plus sediment.

Analyses for metal content in field-collected algae were carried out

on samples of 0.1 g - 0.75 g dry weight which were dissolved overnight in 10 ml concentrated HNO_3 at 85°C, followed by addition of 5 ml 30% H_2O_2 and digestion at 125°C. Samples were filtered through 0.45 µm "Millipore" filters and brought to volume with distilled water. Blanks without algae were run as controls.

RESULT

Algal Populations

Dense mats of the macrophytic green alga Chara cover the pond floors. Diatoms and unicellular green algae are associated with Chara, particularly in summer. Populations of floating algae, which occur along the pond edges, include mainly Spirogyra and the blue-green Oscillatoria, while summer blooms are also comprised of filamentous algae tentatively identified as Rhizoclonium, Ulothrix, and the blue-green Lyngbya.

Uranium and Molybdenum Accumulation by Algae

Table 1 summarizes the results from analyses for molybdenum and uranium in algae samples collected during September, 1979 and January, 1980.

Table 1. Levels of Uranium and Molybdenum in Field-Collected Algae

Location	Algae	U g/m³		Mo g/m³	
		Sept.	Jan.	Sept.	Jan.
Pond 1	Spirogyra Oscillatoria Rhizoclonium	2195	1597	32	316
Pond 2	Chara	352	405	22	ND+
Pond 2	Spirogyra Oscillatoria	651	2915	27	268
Pond 3	Chara	1150	-++	ND	-
Pond 3	Spirogyra Oscillatoria	-	2565	-	117

+ no detectable levels
++ no samples collected

Samples were collected from the three ponds in order to compare metal levels in the macrophytic Chara and in the filamentous algae during the summer and winter seasons, since the ponds' populations varied over the year. Pond 1 contained no evident Chara, while pond 2 contained abundant populations of both Chara and several filamentous algae, particularly Spirogyra and Oscillatoria. Pond 3 contained predominately Chara in the summer and filamentous algae in the winter.

In general, levels of molybdenum and uranium were higher in the filamentous algae than in Chara. While both molybdenum and uranium levels varied widely among the samples, in a given algal sample the uranium content was an order of magnitude higher than the molybdenum. A comparison of values determined for Chara and for a mixture of Spirogyra and Oscillatoria in pond 2 illustrates both these points. Some seasonal variation can also be seen. January samples tended to have higher levels of uranium and molybdenum than September samples. There did not seem to be a correlation between the metal content of a sample and the pond from which the sample was collected.

Uptake of uranium and molybdenum on a short-term basis was studied in Chara and Spirogyra in 24-hour laboratory uptake experiments. Results of two representative experiments are given in Table 2. The ability of the two types of algae to remove metals from solution seems to correspond to the levels of the metals in field-collected specimens. Spirogyra, which had generally higher levels of uranium and molybdenum in the field, was able to absorb significantly higher amounts in the short-term up-

Table 2. Removal of Uranium and Molybdenum from Solution by Algae in 24-hour Uptake

	g/m³ U	% Removed	g/m³ Mo	% Removed
Control	10.1		2.2	
Whole Chara	8.2	19%	2.7	8%
Particulate Chara	8.1	18%	2.2	0%
Control	10.9		3.1	
Whole Spirogyra	7.9	28%	2.7	13%
Particulate Spirogyra	1.9	83%	2.4	24%

take studies. Chara, which contained low levels of molybdenum in the field specimens, showed no detectable absorptive capacity for Mo over 24 hours. Chara cells did absorb uranium over 24 hours, removing about 0.2 mg U per 0.2 g cells (dry weight) in both whole cell and omni-mixed preparations. While increasing surface area by cell-disintegration had no effect on absorption in Chara preparations, the effect on Spirogyra cells was evident for both molybdenum and uranium. Disintegrating cells increased molybdenum uptake 2-fold. Particulate Spirogyra removal of uranium amounted to 1.0 mgU per 0.1 g cells (dry weight). This value, corresponding to 10,000 g/m^3 in the exposed algae, is 10 times higher than in either whole or particulate exposed Chara.

While the whole cells used in the 24-hour uptake studies were living, the time course was too short to follow the effects of cell growth on uptake. Growing cultures were monitered in the long-term study summarized in in Table 3 and Table 4. Cultures of

+ sediment added

Spirogyra and Chara were allowed to grow in light for 13 days. Although the initial amount of algae added was measured (1.1 g dry weight Chara or 0.4 g dry weight Spirogyra) no attempt was made to measure algal mass during the course of the experiment. New growth was observed in Chara cultures

Table 4. Removal of Molybdenum by Algae in Presence of Sediment

Day	Control		Chara		Spirogyra	
	Mo g/m^3		Mo g/m^3		Mo g/m^3

80	2.1	2.8	2.3	1.3	2.7	2.8

+ sediment added

over the 13 day period, while Spirogyra cultures grew rapidly for 4-5 days and then started to decay. All containers were placed in the dark after 13 days, and sediment was added to duplicate culture vessels in order to simulate conditions which would prevail in the field as algae die and sink to the bottom of the pond. The addition of sediment hastened decay of the algae in the dark. Since none of the cultures were bacteria-free, both sediment-containing and sediment-free cultures presumably had increased bacterial activity as decay proceeded. The sediments became black, which is indicative of bacterial sulfate-reduction activity. After 21 days in the Spirogyra cultures and after 49 days in the Chara cultures, the blackening of the sediment surface and presence of algae cells were no longer evident.

Removal of uranium (Table 3) was most pronounced in the Spirogyra cultures. While the presence of sediment did not seem to enhance removal of uranium from solution in comparison to Spirogyra alone, in comparison to the sediment control the algae increased the sediment's ability to retain uranium, with 2.3 g/m^3 remaining in solution in the Spirogyra-sediment cultures and 5.5 g/m^3 in the sediment control.

In the Chara cultures, growing algae had no effect on uranium removal, and

some release of U from the Chara seems to have occured after transfer to the dark (Table 3). However, as Chara decayed in the presence of sediment, levels of uranium fell from 8 g/m^3 on day 14 to 2 g/m^3 on day 49. Less decay of the algae after day 49 allowed re-establishment of an oxidizing zone at the sediment surface, which coincided with partial remobilization of uranium into solution by day 80.

No cultures showed irreversible removal of molybdenum, although Spirogyra cultures reduced molybdenum concentration substantially by day 21 (Table 4). However, molybdenum levels returned to initial values in solution. Chara sediment cultures showed reduction in molybdenum levels when compared to the control.

DISCUSSION

Both the analyses of field-collected algae samples and the evidence from laboratory uptake experiments (Tables 1 and 2) indicate a marked difference in the interaction of uranium and of molybdenum with the algae present in the pond system. Uranium accumulates to a much greater degree than molybdenum in both the filamentous and the macrophytic algae. This difference in accumulation may be due to the roles of the metals in the algal life cycle, or to different interactions between the metals and the algal cell surfaces. Molybdenum can be an essential trace element for algal growth (O'Kelly, 1974), so that it is possible that regulatory mechanisms exist in the cells for maintaining constant levels of the element. Chara in particular shows little variation in molybdenum levels. The field-collected filamentous algae contain higher levels, which may be due to absorption. The ability of Spirogyra to absorb molybdenum onto cell surfaces was demonstrated in the 24-hour uptake experiment. Uranium, in contrast, is generally considered an abiological element (Taylor, 1979), and its uptake is more likely to be governed by physical-chemical factors than by active cellular processes. The uranyl ion has an extremely high affinity for organic material (Jackson Jonasson, and Skippen, 1978), and absorption onto the negatively-charged algal cell surfaces probably accounts for the high levels of uranium in the pond algae. In a study of radionuclide accumulation by Chara species, Marchyulenine (1978) felt that the presence of calcium in the Chara cell wall, chiefly in the bound form of carbonate compounds, reduced the number of cation exchange sites on Chara as compared to other algae. This may be a factor in the lower affinity for uranium in Chara as compared to Spirogyra.

The seasonal variation in both uranium and molybdenum levels also suggests that absorptive processes are important in accumulation of the metals in the algal cells, since extent of absorption is influenced by the amount of metal available per unit of surface area and by length of exposure of the surface to the metal. The September collections represent quickly growing, high density populations; the January collections were taken from sparser populations which, due to the lower growth rate in winter, had a slower turnover time than the summer populations. Knauer and Martin (1973) found that levels of heavy metals were low in marine phytoplankton during periods of high growth rate (algae blooms) due to dilution of the amount of metal per unit mass of phytoplankton. In the case of the algae in the settling ponds, probably the more important factor is the increased length of exposure time to the metals for the winter populations. Hodge, Koide and Goldberg (1979) found that marine macroalgae absorbed uranium, polonium, and plutonium in direct relationship to exposure time.

The phenomenon of increased absorption of metals in dead over living cells has been observed in marine macroalgae for ^{65}Zn but not ^{137}Cs (Gutknecht 1965), in marine plankton for ^{65}Zl but not ^{32}P (Cushing and

Watson 1968), and in Chlorella regularis for UO_2^{2+} (Horikoski, Nakajima and Sakaguchi, 1979). Horikoski et al. (1979) suggested that the increased uptake of UO_2^{2+} in heat-killed Chlorella regularis was due to an increase in absorption sites on the disrupted cell walls rather than to an inhibition of cellular regulatory mechanisms, since whole cells treated with metabolic inhibitors absorbed UO_2^{2+} at the same lower levels as metabolizing whole cells. Absorbed UO_2^{2+} was associated with cell wall and cell membranes, and 81% of absorbed UO_2^{2+} was removable by EDTA washes. In the present study, the particulate suspensions of Spirogyra absorbed twice as much molybdenum and three times as much uranium as whole cells in 24-hours. The main effect of disrupting the cells is probably to increase surface area available for binding, although release of cellular constituents may also be a factor. The suspensions of Chara cells may not have been ground enough to increase the surface area significantly, since the Chara cell is much less fragile than Spirogyra. Ferguson and Bubela (1974) have suggested that fresh particulate algal material should be studied for metal complexing ability, since much organic material in aquatic systems may exist as dead, but not extensively decomposed, material. The ability of particulate suspensions of filamentous algae to concentrate Cu, Pb and Zn was considered by Ferguson and Bubela good evidence for the ability of algae to participate in the formation of metal-rich sediments.

In the pond system, the ultimate fate of uranium and molybdenum accumulated by either living or particulate algal material depends on the retention of the metals in organic-metal complexes and, perhaps more important, on the interactions between metals, algae, and sediment.

While evidence in this study and in those discussed above (Ferguson and Bubela, 1974; Cushing and Watson, 1968; Gutknecht 1965) indicates that dead algae material can absorb heavy metals, several studies on the accumulation of metals by living algae have noted substantial release of metals from algae as cells died (Filip, 1979; Jennett, Hassett and Smith, 1977; Laube, Ramamoorthy and Kushner, 1979). Laube et al. (1979) gave evidence in their study of Cd and Cu uptake by Anabaena that cell lysis released Cd and Cu as organic complexes. Whether such organically-bound metals could be reabsorbed onto sediment particles was not investigated. Filip (1979) observed that mixed algal cultures could remove 50-75% of the Cd and Cu in a wastewater treatment system, but that sand filtering increased removal to 98 to 100%. It is possible that the sand particles not only adsorbed metals ions from water but also stabilized the metals accumulated by the algae by an exchange of adsorbed material between algae and sand particles.

Algae cells come in contact with the sediment primarily as decomposing material. Studies on aerobic and anaerobic decomposition of a wide range of algae types indicate that both processes result in mineralization of about 60 percent of cell material, while the remaining faction persists as particulate material whose carbon content is similar to the starting material (Fallon and Brock, 1979; Foree and McCarty, 1970; Weir, 1978). This refractory material could be a source of organic material for long-term complexing of metals in sediment.

When sulfate levels are high in anaerobic decomposition, sulfate reduction accompanies decomposition of algae (Foree and McCarty, 1970). Taylor (1979) has pointed out that the production of hydrogen sulfide by sulfate-reducing bacteria may increase the absorption of uranyl ion by organic material in sediment, since iron and other sulfide-forming metals could be desorbed from the organic material

and increase the possiblity of uranium sorption.

The patterns of retention and release of uranium and molybdenum in the 80-day study using Chara and Spirogyra suggest that the maintenance of reducing conditions is critical in the sequestering of both metals in the sediment. In the model system, the period of algae decomposition was associated with increased bacterial activity and an enhancement of reducing conditions in the sediment-containing cultures. The cultures of algae without sediment probably decomposed mainly in aerobic conditions. The period following decomposition was characterized by release of molybdenum and uranium back into the water. The release of molybdenum was surprising, since sulfides which are formed during sulfate reduction can form highly insoluble molybdenum sulfide. It is possible that molybdenum was precipitated in the reduced Mo (IV) state but not as a sulfide, so that release occured as molybdenum re-oxidized. The Chara cultures contained twice as much material on a dry weight basis as Spirogyra, which may have contributed to the greater retention of molybdenum in the Chara sediment.

Algal material contributed to some extent to the retention of uranium in sediment. Evidently reduction of uranium to the insoluble U (IV) ion played a part in removing uranium, with absorption onto organic material also a possible mechanism. While Chara material alone was unable to affect uranium levels in the water significantly, the presence of the decaying algae in the sediment resulted in retention or uranium in the sediment. On the other hand, Spirogyra contributed to removal of uranium in algae cultures without sediment, possibly by absorbing uranium onto cell surfaces more effectively than Chara.

The mine-water of the study system contains 700 g/m^3 sulfate and a large population of sulfate reducing bacteria (2.5×10^2 g^{-1} dry weight) in the pond sediments (Brierley and Brierley, in press). The conditions present in the sediments, high sulfate concentrations, available organic matter from algae decomposition, and a reducing environment (Eh,-350mV) favor growth of Desulfovibrio and Desulfotomaculum. Laboratory experimentation has indicated that enhancement of growth and sulfate reduction by these microbes results in removal of uranium, molybdenum, and selenium from solution (Brierley and Brierley, in press). However, a recent report (McCready and Krouse, 1980) has indicated that the activity of sulfate reducing bacteria may also lead to mobilization of radium bound in sediments with barium sulfate. This observation needs further investigation to determine if the beneficial activity of these microbes in sequestering various pollutants may also have a deleterious aspect in regard to radium release.

The biological components of the wastewater treatment system effective in pollutant removal from mine water of two Kerr-McGee Corporation mines is a complex association among diverse microbial populations. The algae, Spirogyra, Oscillatoria, Chara plus others, concentrate soluble and particulate pollutants, and convert CO_2 and solar energy to reduced organic compounds which serve as substrates for the bacteria. Upon death, the algae settle to the pond bottom sediments where decomposition occurs by aerobic and anaerobic bacteria. Some unknown amount of the pollutants may be released and some amount sequestered in a recalcitrant organic fraction. The degradative activities of the bacteria will result in consumption of oxygen, with establishment of reducing conditions and production or fermentation products such as organic acids and alcohols. The fermentation products in turn serve as energy sources for Desulfovibrio and Desulfotomaculum which reduce sulfite to sulfide. The sulfide can then act as a reducing agent for hexavalent

uranium and precipitate other metals as sulfides.

There are other biological activities and physico-chemical processes which also lead to pollutant removal. The relative contribution of each active component to the system is yet to be established.

ACKNOWLEDGEMENTS

This research was supported by the United States Bureau of Mines, project J0295033, and the New Mexico Water Resources Research Institute grant 1345639. The authors sincerely thank Mr. James Cleveland and the Kerr-McGee Corporation for their cooperation and permission to study their mine-water treatment system.

DISCUSSION

Question - What is the pH of the mine water, algae-ponds and the laboratory-study system?
Answer - The mines'-water pH average 6.95 and 7.05. The pH of the algae-ponds averages 7.28 to 7.52. The pH was 7.8 for short term batch-reaction experiments. Algae cultures in the laboratory were initially pH 7.7 - 7.9; the pH increased to 8.0 - 8.2 during growth and decreased to 6.0 when Spirogyra died and decayed and pH 7.6 with decaying Chara. When sediment was present in the culture flasks the pH remained at 7.6.

Question - What is the effect of pH change on pollutant removal?
Answer - At low pH values hydrogen ion competes with cations for adsorption sites on cell-surface biopolymers resulting in decreased absorption. In conditions of pH above 5, uranyl-ion absorption may depend on presence of anions (e.g., $H_2PO_4^-$, $HPO_4^=$, HCO_3^-) which form complex ions with uranyl-ion not absorbed by cell surfaces. At low phosphate or bicarbonate concentrations, absorption of uranyl-ion is pH-independent above pH 5. In acidic environments (e.g., pH 3.5) the algae populations found active in the mine-water treatment system would not grow or function.

Question - What are the optimum conditions for sulfate-reducing bacteria (Desulfovibrio and Desulfotomaculum)?
Answer - The sulfate reducing bacteria can be found which tolerate extreme physical conditions. These microbes can grow at temperatures at or below 0°C to 70°C with optima of 25-30°C for Desulfovibrio and 35-55°C for Desulfotomaculum. The sulfate reducing bacteria can grow at all salinities from near zero to saturation. The Desulfovibrio are more tolerant of salt that the Desulfotomaculum. These microbes are strict anaerobes; the redox potential of the environment should be - 100 mV or less. pH 7 to 7.6 favors growth. Most sulfate-reducing bacteria have no special requirements for organic growth factors. The substrates apparently preferred as carbon sources are a few C_3- and C_4- fatty acids.

Question - What precent removal of the various pollutants occurs in the mine-water treatment system?
Answer - The field-site system reduces uranium 70% and selenium and molybdenum by 60%.

CONTROL OF HEAVY METALS IN LEAD INDUSTRY EFFLUENTS BY ALGAE AND OTHER AQUATIC VEGETATION

Nord L. Gale* and Bobby G. Wixson**

Proc. International Conference on
Management & Control of Heavy Metals
in the Environment, September, 1979
London

ABSTRACT

The lead mining industry in Southeast Missouri, U.S.A. has successfully utilized algae and aquatic vegetation in tailings ponds or experimental stream meanders as a control method to remove heavy metals such as lead, zinc, copper and cadmium from mine-mill and smelter effluents. Research has indicated that the heavy metal removal has been accomplished through the physical trapping of suspended mineral particles and subsequent chelation to the numerous anionic sites within the cell wall resulting in the displacement of divalent or monovalent cations normally associated with the cell envelope. Some heavy metals may also be transported to the interior of the cell in membrane lined vessicles.

Laboratory studies on mixed algal cultures have demonstrated cation exchange capacities in excess of 640 microequivalents per gram (dry weight). The displacement of considerable quantities of normal cations by lead and zinc does not seem to cause physiological impairment and the amount of heavy metals tolerated was found to vary with the species studied.

The ability of algae and aquatic vegetation to utilize nutrients and remove heavy metals from mine-mill and smelter effluents are discussed with emphasis on their potential use by industry for the management and control of heavy wastes.

TEXT

The Missouri "New Lead Belt" in the U.S.A. continues to be the largest lead producing district in the world: 508,857 metric tons in 1978, or 87% of the total U.S. production. The location, development and impact of this industrial enterprise have been previously documented in the intensive interdisciplinary study funded by the National Science Foundation (Ref. 1).

The Buick Mine and Mill complex, owned and operated by AMAX Lead Tollers, Inc., is the largest lead mine in the world with annual production in 1978 of 167,421 metric tons of lead concentrate. It also produced 62,495 metric tons of zinc concentrate. At this mine, water is pumped from underground operations at a rate of 5.5 mgd, with 4 mgd being used in the surface milling operations. Excess mine water and mill wastewater (tailings) are piped to a large 425 acre-ft lagoon approximately 2 miles away, situated at the headwaters of Strother Creek.

After operations began, there was considerable alteration in the quantity and quality of water entering Strother Creek. Excessive accumulation of rock flour and nuisance algal blooms extended several miles downstream, and the rate and possible extent of environmental contamination by vagrant heavy metals were not known. Early studies conducted on Strother Creek showed that aquatic vegetation blooming throughout much of the year effectively scavenged suspended or dissolved

*Associate Professor Life Science **Professor of Environmental Health
University of Missouri-Rolla, Rolla, Missouri U.S.A.

heavy metals and other vagrant particulates. Submerged algae and rhizophytes were found to contain extraordinary amounts of heavy metals at collection sites in the vicinity of industrial tailings lagoons, decreasing in metal content at downsteram sites. Unfortunately, however, unsightly blooms of metal-laden vegetation often extended several miles downstream, stimulated by the release of abundant nutrients by industrial operations.

With the large volumes of mine-mill wastewaters and the availability of land AMAX chose not to recycle but, in an attempt to improve water quality of the receiving stream, constructed a system of artificial meanders and a final sedimentation pond below the main tailings lagoon (See Figure 1). These alterations, completed in 1972, provided a long, meandering, shallow stream bed, encouraging the growth of aquatic vegetation and removal of suspended particulates and nutrients prior to discharge to public streams. This wastewater treatment scheme has operated successfully for the past 7 years. The effectiveness of the treatment system is indicated in part by Figure 2 which shows lower concentrations of heavy metals observed in aquatic vegetation specimens collected downstream after installation of the secondary meander system. The number and severity of nuisance algal blooms observed in Strother Creek have been reduced dramatically. Benthic conditions in the public receiving stream have returned to pre-industrial levels so that stream quality closely resembles that observed in control Ozark streams.

Within the meanders and final settling pond, aquatic productivity is excellent. Stocking of these areas with catfish, bass, and bluegill has been very successful, much to the delight of area fishermen. Dominant producer organisms within the meanders include: Potamogeton, Typha (cattails), Cladophora, Rhizoclonium, Hydrodictyon, Spirogyra, and seasonal blooms of Oscillatoria. Typical consumers which abound throughout the treatment system include crayfish, tadpoles, frogs, bluegills, catfish, smallmouth bass, carp, and a variety of aquatic insects. Although absent in the upper meanders, snails are abundant in the final settling pond and discharge areas.

The mechanism by which aquatic vegetation binds heavy metals has been the subject of further investigation (Ref. 2). Some heavy mineral particles are obviously physically trapped by roots, stems and filaments of stream vegetation. Numerous anionic sites on and within cell walls of exposed vegetation participate effectively in a process of cation exchange with the heavy metals. Those available metal ions which possess greater charge density displace other normal cations of lesser charge density such as Na^{+}, K^{+}, Mg^{++}, and Ca^{++} commonly associated with cell walls, membranes and internal structures. Laboratory investigations have confirmed the displacement of approximately equivalent quantities of normal cellular cations as soluble lead salts are bound to surfaces of algal filaments and partially decomposed leaf litter. Even relatively insoluble mineral particles (galena) have been found to be dissociated at the surface of algal filaments and subsequently bound within the matrix of the adjacent cell walls. Saturation of living and autoclaved algae (Rhizoclonium, Cladophora, and Spirogyra) by applied lead solutions indicate cation exchange capacities (CEC) of over 640 microequivalents per gram dry weight. In comparison, partially decomposed leaf litter displayed CEC of approximately 1800 microequivalents per gram dry weight.

Despite elevated metal concentrations in sediment, stream vegetation and litter, no indication was found for biomagnification or concentration of heavy metals in stream consumer organisms, either within the meander system or further downstream (Ref. 3). Research indicates that lead bound to aquatic vegetation or debris apparently passes through the digestive tract of common herbivores, remaining predominantly with the

partially decomposed plant matter. Mucous membranes and chitinous coverings of aquatic consumers can compete in the process of cation exchange with heavy metals, though not as efficiently. Quantities of heavy metals associated with gills, skin, exoskeletons, and mucous membranes of consumer organisms abundant within the meander system apparently are quite tolerable.

Many of the potential problems associated with large-scale lead production are alleviated by the chemical and physical conditions imposed by the geologic regime and the hard, naturally alkaline stream waters of southeastern Missouri. Reduced solubility of heavy metals under these conditions is an obvious convenience and environmental protection in a region of intense mineral exploration. The abundant vegetation within the region, and especially in the vicinity of industrial operations undoubtedly plays a role in scavenging particulate matter and effectively binding potentially toxic heavy metals. This not only restricts and limits rates of lateral dispersion from areas of contamination, but also limits availability of toxic heavy metals to organisms, tissues and structures more physiologically sensitive.

Further studies are being conducted to evaluate the use of aquatic vegetation as a method of controlling heavy metals in industrial effluents on a broader scale.

Shallow beds of algae (algal meanders) have proved to be highly effective at removing heavy metals and organometallics from lead-zinc mine and mill wastes. A laboratory-scale research program was initiated to determine conditions under which algae were most effective at concentrating significant quantities of As, Cd, Cu, Hg, Ni, Pb, or An, for the purpose of potential application of the meander technology to new types of wastewater-metal problems.

Studies were performed on 20 species of algae to determine interactions of experimental variables affecting metal adsorption, species and strains of algae, type, form, and concentrations of metal, pH, culture age, micronutrient composition of culture medium, exposure to metal, and light intensity and exposure period. These numerous variables were studied by means of a rapid analytical technique, the Titertek™* supernatant collection system, to determine the adsorption of metal radionuclides.

Metal removal was observed to be fast (three hours), young growing cultures were seen to be most effective, and concentration factors $> 1 \times 10^4$ were observed. The pH had little effect on accumulation of metals except lead. Heavy metals could be stripped from algal mats with 0.01 M EDTA or 0.1 N HNO_3. Ca and Mg were not effective competitors for the binding sites of Hg, Pb, and Cd. Neither Zn nor As was bound significantly at any pH. Experimental and literature data indicate that algae remove certain metals economically from a variety of waters and that the meander system can be used to recover these metals for processing.

This report is submitted in fulfillment of Grant No. R804734 by Syracuse University under the sponsorship of the U. S. Environmental Protection Agency. This report covers the period from September 13, 1976 through January 1, 1979 and work was completed as of June 30, 1979.

This Project Summary was developed by EPA's Industrial Environmental Research Laboratory, Cincinnati, OH, to announce key findings of the research project that is fully documented in a separate report of the same title (see Project Report ordering information at back).

Introduction

Effluents from secondary lead smelters are a major source of heavy metals in the aquatic environment. These effluents are frequently low in pH and contain a wide range of heavy metals. The largest single heavy metal constituent is, of course, lead. Relatively large amounts of zinc, cadmium, arsenic, copper, and other toxic cations may also be found, along with a wide variety of anions often associated with these metals (chloride, sulfate, nitrate and chromate for example). Lead smelter effluents also contain toxic trace organics generated when batteries and other materials are crushed, and the heavy metals are removed from their plastic encasements. The fact that heavy metals are dangerous in the aquatic environment has been well documented in the literature.

To protect the environment, the discharge of heavy metals must be minimized. One approach is to apply the type of algal-meander treatment system cur-

rently in use for treating mine and mine-mill wastes at one site in the new lead-belt region in southeast Missouri—the world's largest lead mining region. A detailed laboratory study of the factors influencing heavy metal accumulation by algae is the subject of this investigation and an attempt has been made to evaluate the feasibility of using algal meanders to remove a variety of heavy metals.

Description of the Meander Process

In the Missouri algal-meander system, mine and mill wastes were treated in a standard tailings pond followed by a series of shallow meanders in which the growth of algae is encouraged. These algae grow, utilize the waste millings reagents and trap heavy metals, both particulate and dissolved, on their surface. When the algae mat breaks loose, it is then trapped in a settling pond at the end of the meander system. The pond is equipped with baffled weirs which prevent algal overflow into the receiving stream. Based on total heavy metals removed, the system is more than 99-percent effective. Dissolved heavy metals are also removed to levels well below U.S. Public Health Service drinking water standards. Past work has shown also that lead in its highly soluble acetate form is removed effectively by the algae.

To date, the algal-meander system has been used to treat only one waste, a combined lead-zinc mine and mill waste in the new lead-belt mining region. Since 1971, this region has been the site of a large interdisciplinary investigation, supported by the National Science Foundation, of environmental pollution by lead and other heavy metals. It was confirmed in 1974 that below the AMAX-Homestake Lead Tollers, Inc., mining mills, severe stream degradation and heavy metal buildup was occurring. The meandering system was built to a full operating scale and as a result the stream was returned to essentially pre-mining conditions. The history of this treatment system and the quality of the water in receiving streams has been well documented for lead and zinc. This technology, however, has not been applied to wastes containing other toxic metals. This has been largely due to the lack of information on the system's range of application and the newness of the technology. The ability of algae to concentrate heavy metals from their aqueous environment has been reported by radioecologists examining debris from nuclear tests, chemical geologists attempting to explain low-grade deposits of metal, and ecologists concerned with the self-purification of streams below mining operations. While these observations are clearly valuable, a more detailed knowledge of the interaction between algae and heavy metals could aid in understanding these processes. A systematic study of these interactions has been difficult because a wide range of variables affects metal accumulation by algae. These variables include the length of the exposure period, the type of metal, oxidation states, pH, salinity, and presence of organic pollutants. To understand the factors influencing metal accumulation by algae in the meander system, laboratory studies were initiated with pure cultures of representative species from other laboratories and from the algal culture collection at the University of Texas.

Conclusions

The ability of representative algae to concentrate large quantities of specific heavy metals was demonstrated by adapting the Titertek™ supernatant collection system (Flow Laboratories, Rockville, Maryland) for assaying radionuclides of heavy metals. This technique permitted the simultaneous study of several factors affecting heavy metal accumulation and provided a sufficient number of replicates for statistical analysis. Algal-metal combinations used in batch studies are presented in Table 1.

The removal and concentration of heavy metals from their aqueous environment by algae was first studied in detail in the 1950s and 1960s as part of the problem of the release of nuclear debris from weapons testing, and from reactor cooling water effluent. Scientists took advantage of the released isotopes, as well as newly developed analytical techniques, to study pathways of various elements in the environment. One early result of this work was the observation that certain isotopes were concentrated by biota to a much greater extent than the concentration of that isotope in water. From these observations came the concept of the concentration factor (CF) such that

$$CF = \frac{C}{C'}$$

where C and C' are the concentration of the radionuclide in the aquatic organism and in the aqueous medium respectively. The concept is also applicable to stable isotopes (Polikarpov, 1966).

Calculation of concentration factors for heavy metals revealed significant differences between species of the same genus and between strains of the same species (i.e., *Nostoc*). Some species regularly had concentration factors of 1×10^4. In general, young cultures exhibited very much higher concentration factors than old cultures. Most of the metal removed by algae can be removed by a rinse with 0.01 M ethylenediaminetetraacetic acid (EDTA) or 0.1 N nitric acid (HNO_3). This information suggests that surface adsorption sites are the principal repository for the metallic ions or particles.

The ability of algae to remove metals is generally in this order: mercury > lead > cadmium. Neither zinc nor arsenic was removed significantly at any pH during a three-hour exposure. The presence of chelating agents in the medium (such as EDTA) inhibited the removal of the heavy

metals. Calcium and magnesium were not effective competitors for the binding sites of mercury, lead, and cadmium. There was remarkably little effect of pH on metal accumulation in the range of pH 5 to 8, when young cells were employed. Lead was the principal exception because it was removed more efficiently at pH 4 to 5 than at other pH values.

The removals of lead and mercury from nutrient solution by algae are found to be rapid phenomena, usually accomplished in three hours or less at room temperature. If the cells were placed in buffer after the initial adsorption of lead, a limited, slow release of lead occurred for a few hours, perhaps while some surface polymer-lead complexes were released from dead or dying cells. Mercury was removed from solution in nearly identical fashion by two strains of *Nostoc* and showed little evidence of being released. In the control wells without algae there were reproducible losses of ^{203}Hg that occurred within the first 24 hours at pH 6. This may be related to reports in the literature claiming volatilization of mercury by algae.

Chlamydomonas (a green flagellated form) proved to be dramatically superior to all other species in its ability to remove lead. Concentration factors for the organism of 1.9×10^4 were noted. This organism showed essentially the same concentration factor for lead in the pH range of 4 to 9. In other experiments, *Ulothrix* and *Chlorella* had concentration factors for cadmium greater than 10^4.

The empirical successes of the algal-meander system for removing lead from surface waters can be explained in part by the concentration and sequestering of lead and cadmium on the surface of algal cells. Very little heavy metal was leached from these cells at pH 5 to 9 in the presence of divalent cations and other inorganic constituents of algal growth media.

Results

Algal Growth

Algal growth for 20 species provided a representative selection of algae for the experiments. Some species proved impossible to culture and others exhibited unusual rates of growth. Table 2 reveals that no growth was obtained from any form in soil-water media. The choice of African violet potting soil was probably unfortunate because this soil is high in humus. Success with this medium depends on the selection of a garden soil with a medium humus content.

A few algal forms were characterized by unusual growth rates. *Mougeotia* and *Zygnema* grew only slowly and to a low final biomass. *Nostoc* 31, *Nostoc* W and *Gleotrichia* exhibited a long lag phase. For each of these forms, inoculation was followed by about 15 days of apparent inactivity. After this period, growth to a useful final biomass was rapid. For these forms, then, no young culture data are available.

Batch Studies

The results of the batch studies are presented in Figures 1 through 8. The figures show the concentration of metals in the sample as a function of the time the samples were withdrawn from the culture. It should be noted that, for reasons of clarity, not all data points are shown on the figures.

Arsenic III—The data show no obvious trends in the removal of arsenic III. The highest removal (about 35%) was accom-

Figure 1. *Uptake of arsenic (III) by various algae.*

Figure 2. *Uptake of arsenic (V) by various algae.*

plished by *Chlamydomonas*, which also had the lowest biomass (0.12 mg/ml).

Arsenic V—There are no obvious trends in the removal of arsenic V. Most experimental values are too close to the control value to be considered significantly different. The lowest experimental value (16 µg/ml, compared to a control value of 20 mg/ml) was attained by *Nostoc* 586, which had among the highest biomass (0.40 mg/ml).

Cadmium—Cadmium was likewise not dramatically removed by the algae used in this part of the study. The lowest experimental values (about 10 µg/ml) were achieved by *Ulothrix*, which had the highest biomass (0.34 mg/ml). That the acid rinse for both *Ulothrix* and *Nostoc* 586 (with the next lowest experimental value) had high concentrations of cadmium indicates a surface adsorption mechanism for cadmium removal.

Copper—The highest removal of copper (about 30% compared to the controls) was attained by *Gleotrichia*, which had a biomass of about 0.14 mg/ml. This alga, though usually a dark brown mass of filaments, turned greenish on exposure to copper.

Lead—Lead appeared to be removed by all the forms studied in this experiment, with removal (compared to the 18-hour control) of from 15% for *Spirogyra* to about 87% for *Oscillatoria*. The green filamentous *Ulothrix* showed high values of lead removal, and the morphologically similar *Spirogyra* showed values little different from the controls, even though both algae had nearly identical biomasses. The high values of lead in the acid rinses suggest again a surface adsorption.

Mercury—The most dramatic removal of mercury was accomplished by *Nostoc* 586, which had an experimental value of 6 µg/ml as compared to the control value of 34 µg/ml after only three hours. Again the values of mercury in the acid rinses were high.

Nickel—Although all algae seemed to exhibit some removal of nickel (17% to 37% after 24 hours), no trends could be discovered from the data.

Zinc—The algae that seemed to accumulate zinc were *Spirogyra* (with 41% removal after 18 hours) and *Nostoc* 586 (with 37% removal during the same length of time). Again, the acid rinses of these two algae had high values of zinc, suggesting surface adsorption sites.

Discussion of Project Results

With the exception of zinc, these results show reasonably good agreement with the literature, with all concentration factors between studies agreeing within a factor of 2 to 3.

Previous studies also examined the kinetics of heavy metal accumulation by algae and in general show that uptake was an extremely rapid phenomenon. The results of the 24-hour experiments in this study clearly confirmed the earlier observations in this regard. The negative results for the cadmium experiments cannot be explained at this time.

One obvious manner in which the present study extends previous work is the calculation of concentration factors for species of algae previously unstudied. These data were obtained under identical conditions and record both intraspecific (in the case of *Nostoc*) and interspecific differences in heavy metal accumulation by algae. New data are provided on the effects of culture age, and initial pH

Figure 3. *Uptake of cadmium by various algae.*

Figure 4. *Uptake of copper by various algae.*

during the labelling period, on the accumulation of heavy metals by algae.

The present study about doubles the number of algae for which concentration factors for cadmium have been determined. This is not only important to waste treatment applications, but also to environmental impact studies. Also noteworthy is the close agreement of concentration factors from the literature with those of this study, with CFs on the order of 10^3 common to both. What is not immediately apparent is the generally lower CFs for the blue-green algae. In fact, three 10-day old cultures of blue-green algae, *Nostoc muscorum* A, *Nostoc* H and *Schizothrix calcicola* did not remove cadmium significantly at any pH, while only one green algae, *Mougeotia*, showed such negative results. Although the total number of species examined is small, the present study suggests that green algae are somewhat more efficient at accumulating cadmium than the blue-green algae.

Concentration factors for lead are generally on the order of 10^3 to 10^4 for all algae studied. All the blue-green algae screened were successful at removing lead at least at one pH, while the diatom *Navicula pelliculosa* and the green *Chlorella* and *Scenedesmus obliquus* were successful at accumulating lead at any pH. *Chlamydomonas* proved to be the most efficient at removing lead from solution.

Mercury was again demonstrated to be concentrated avidly by most species of algae. Every organism screened in this study removed mercury at least at one pH, with concentration factors on the order of 10^3 and 10^4. Algae may be one of the most effective means for removing this element. Algae can reduce mercuric ion to elemental mercury which is subsequently volatilized to the atmosphere. The question might arise whether the same phenomenon occurred in these experiments, giving artifically high concentration factors. Although the possibility cannot be denied categorically, the short time scale of these experiments (three hours) and the quiescent conditions under which the plates were held would argue against loss of very much mercury to the atmosphere. This is especially true since most other studies employed aerated cultures and a time scale of several days. It has also been reported that the reducing factor(s) were extracellular. Since the algal cells in the present study were washed and resuspended in distilled water before introduction to the assay plates, the concentration of reducing factor(s) would be diminished, at least initially. However, the phenomenon of mercury reduction and volatilization by algae clearly deserves further study.

Another contribution of this work was the systematic study of the effect of pH on heavy metal accumulation. The studies cited from the literature were generally field observations, during which the pH of the surroundings varied naturally, or were laboratory studies where the culture media characteristically determined the pH of metal uptake, and therefore, uptake across a wide variety of pH conditions could not be determined. In general, those algae which are most proficient at removing metals will remove them over a wide pH range. For example, *Chlamydomonas* removes lead across a pH range from 4 to 9 at about the same efficiency (0.69-0.80) while the less effective alga *Mougeotia* removes lead only at pH 9 and

Figure 5. *Uptake of lead by various algae.*

Figure 6. *Uptake of mercury by various algae.*

then only at an efficiency of 0.29. Clearly *Chlamydomonas* is more competent at removing lead from solution.

Other observations made during this study tend to confirm and extend suggestions made by earlier workers. It has been hypothesized that the flagella of *Platymonas subcordiformis* provided the sites for a significant fraction of the lead taken up by this algae. While this hypothesis was not specifically tested in the laboratory, the dramatic superiority shown by *Chlamydomonas* in removing lead, as compared to the other algae evaluated combined with the fact that *Chlamydomonas* was the only flagellated form used, argues for the importance of the flagella as sites of lead accumulation.

Perhaps one of the most important contributions of this work, however, was the adaptation and development of microtiter equipment, especially the Titertek™ supernatant collection apparatus, to the study of the problem of algal uptake of heavy metals. The technique and procedures developed during the course of this study have already provided usable data on a relatively limited number of variables. Future work will no doubt utilize the rapidity and sensitivity of the technique to accumulate more data covering a wider range of variables.

Recommendations

The remarkable ability of selected algae to concentrate heavy metals on their cell surfaces suggests that the use of intensive algal culture may be a very practical way to reclaim wastewater and/or recover useful quantities of metals. Several directions for future research and development are clearly indicated before this potential can be realized:

1. The glycocalyx—i.e., the mucopolysaccharide and protein capsule—surrounding all algae must be isolated from metal-avid species and further studied for its biochemical structure, exchange capacities, and biphasic physical properties. With these data in hand, it is practical to search for organisms with glycocalyces having desirable properties for the adsorption of metals.
2. If algal beds are to be maintained on a continuing basis, it will be necessary to follow the reproductive capacity of the organism(s) in the presence of excessive levels of metal. In fact, it may be necessary to devise schedules for metal adsorption that are followed by regeneration at low metal levels.

   The present meander technology depends entirely on the presence of naturally occurring wild algae, probably growing as a mixed flora. Since some of the species may have concentration factors in excess of 1×10^4 under certain conditions, and others may not concentrate metal at all, it appears profitable to encourage the former by selective algal farming. Simple enrichment culture techniques are feasible for the meander manager.
3. A screening operation should be devised with the objectives of finding natural or induced mutants that a) have accumulation coefficients one or more orders or magnitude greater than wild types, b) exhibit greater selectivity for a particular metal ion than the wild types, and c) tend to

Figure 7. Uptake of nickel by various algae.

remain in their benthic form rather than in their free-floating form. The blue-green algae may be the better choice for this work because they are usually more metal-avid than green algae, and because they are haploid. The latter characteristic makes it easier to induce mutations and to select for variants than in diploid organisms.

4. Almost no data are to be found concerning the maintenance of beds of benthic algae on a continuous basis. Experiments are needed to learn the long-term consequences of heavy metal accumulation in such beds, to monitor detention and release of metals during chronic exposures, and to study the detachment of benthic cells coated with heavy metals.
5. Methods must be devised for systematically discharging metals, or for otherwise recovering them, from meander beds. Simultaneously, it must be determined whether or not it is feasible to recycle the algal cells as inoculum or feedstock after they have been stripped of metal by chemical washing.
6. Investigation of practical questions regarding the suitability of metal-stripped secondary sewage effluent for agricultural purposes must be examined. Conversely, the efficacy of sewage as a dependable nutrient source for algae has not been established. Certainly, the presence of oil, cyanates, solvents, etc., could be expected to interfere with the productive synthesis of the glycocalyx adsorptive surface.
7. The effects of light, temperature, and salt concentration have not been evaluated on a continuously operating meander. Quantitative data have not been collected on the optimum output of glycocalyx because the factors which stimulate it are essentially unknown.
8. Future work should determine whether or not an appropriate substitute can be found for the algal cells in the meander (aggregates or other surfaces coated with semi-purified glycocalyx, for example). This search might provide a renewable and/or strippable surface that would eliminate some of the vagaries associated with the maintenance of open algal cultures.
